These contrasting approaches have historical roots: Analog thinking relates to early work on the automation of continuous operations such as those practiced in the process industries, while binary thinking grows out of attempts to automate piecewise operations such as those used in the production industries.

Process automation as now practiced in industry involves the convergence of both approaches. This applies to processes being automated and to the automation equipment itself, but not to the mathematical apparatus.

Operations. Operations that have long been automated by open-loop control methods are now being operated with closed-loop methods as well; an example is the motion programs of industrial robots.

Process engineering, a classical domain of closed-loop control, now makes increasing use of open-loop control, both for the automated startup and shutdown of continuous processes and for automated batch production.

At the same time, a trend toward higher-level optimization of the entire production process, with the goals of improved efficiency and flexibility, is apparent in all areas of industry. The result is generally coupling of subprocesses in the sense of material streams, energy, and information. Process automation thus calls for a holistic examination of continuous and discrete subprocesses, analog and binary process variables, and continuous and sequential operations. (This section does not deal with a third class, object-related operations [362], in which individual, identifiable objects pass through the process. As far as process engineering is concerned, this concept figures chiefly in high-level production automation; examples of "objects" are charges and production campaigns. See also Chap. 2 and Section 4.5.)

Automation Equipment. Just as continuous and discrete subprocesses have been linked into "hybrid" processes, automation equipment has also undergone a merger with classical measurement and control devices (Fig. 104 A) becoming components of integrated automation systems (Fig. 104 B). This development has, however, been driven less by user demand for integrated process automation than by technological advances in instrumentation and control. Mechanical, pneumatic, hydraulic, and electromechanical devices have gradually had to give way to microprocessor-based electronics. Hence the step from consistent instrumentation and control devices to integrated process automation systems was obvious.

Figure 104. Application areas of automation systems
A) Classical automation devices; B) Modern automation systems

The adoption of these systems by users has been aided by the appearance of two variants that use software to mimic the operator interface of classical instruments and controls (Fig. 104 B):

1) The programmable logic controller (PLC) for users oriented toward open-loop control in the production industries. Programming may be performed graphically with ladder diagrams, which are similar to the schematic diagrams of relay-based control systems.
2) The process control system (PCS) for users oriented toward closed-loop control in the process industries. The PCS interface can, for example, imitate conventional control stations with live flow diagrams and controller front panels (see Section 5.2).

The combination of first-generation PCS and PLC into integrated "hybrid" process automation systems has led to a second generation of process control systems [363].

Mathematical Methods. A hybrid system consisting of a hybrid process and a hybrid automation system can be simplified by splitting it into a continuous, "analog" part and a discrete, "binary" part (Fig. 105). These subsystems have common structural properties: They contain internal feedback paths and must be treated as dynamic systems with memory elements.

Figure 105. Hybrid system
Input and output signals connect the system to surrounding systems (e.g., systems on higher and lower levels; operator interfaces)

The mathematical methods applied to the two classes of systems have not yet converged [364], mainly because the theoretical techniques are at far different stages of development.

For continuous systems (and also for the closely related sampling systems), control theory offers a polished, complete, and proven mathematical toolkit. For the modeling, analysis, and synthesis of dynamic discrete event systems, in contrast, there is only a rudimentary selection of diverse methods, including switching algebra [361], Petri nets [365], Boolean differential calculus [366], and theory of automata [367].

Terminology. The foundation of binary control is switching algebra [361], which works on two-valued or logical variables. Its axioms establish the elementary logical operations conjunction (AND), disjunction (OR), and negation. Figure 106 shows schematic symbols for the hardware implementations of these operations. Other basic operations are derived from the elementary ones: NAND, NOR, equivalence, antivalence (exclusive OR or EXOR operation), and implication. Combining the basic operations generates switching functions, the implementations of which are called combinatorial circuits or logic controllers. The rules of switching algebra permit the mathematical analysis of networks. The Quine – McCluskey method can be used for the minimization of given logic functions [368].

If a combinatorial circuit contains internal feedback paths, memory elements (flipflops) can arise (Fig. 107). In this way, a sequential circuit or sequential controller is obtained. There are two classes of flipflops: level-operated and edge-triggered. In level-operated devices, the output can change its state as soon as one input state changes; in edge-triggered circuits, the output can change its state only when a certain (e.g., positive) edge is presented at a certain input, called the clock input. If, along with the logic functions, a sequential circuit contains only edge-triggered flipflops whose clock inputs are all driven by a central system clock, it is said to be a synchronous sequential circuit (since all the memory states can change only in synchrony with the edge of the clock pulse). Otherwise, the sequential circuit is said to be asynchronous.

A systematic design procedure exists for synchronous sequential circuits. The starting point is a graphical description of the problem, called the state diagram [369]. The technique does not, however, insure a minimal realization of the sequential circuit. State diagrams are also unsuitable for the analysis of complex circuits, since a

S set input; R reset input (with priority over S)

sequential circuit with n memory elements can have up to 2^n states.

Besides the combinatorial and memory elements, there is a third type of basic functional element: timers, which shortens, lengthens, or delays binary impulse signals. They are of very minor importance in the theoretical analysis of binary control systems but are frequently used in practice.

The program of a control system means the establishment of all signal-processing functions. This can take either of two forms. In a wired-program controller, the functions are established by hardware connection of the individual functional elements. If the connections can be altered in a simple way, the controller is said to be reprogrammable; otherwise it is called fixed-programmed.

In a stored-program controller (or programmable logic controller, PLC), both the functional elements and their connections are simulated in software on a digital computer. The control program is thus part of the computer program. The program for a RAM-programmed controller is stored in read – write memory (random-access memory, RAM); that for a programmable controller with exchangeable memory is stored in read-only memory (ROM).

A PLC includes a digital computer and is thus essentially a synchronous processor. It can, however, be used to simulate combinatorial circuits, asynchronous and synchronous sequential circuits, timers, and also analog signal-processing elements such as controllers, or any combination of these, to a very good approximation. It accordingly represents the most flexible and advanced way of solving all control problems, and it is the most cost-effective technique for all complex control problems.

A number of text-oriented and graphics-oriented languages are available for the specification of control tasks and the programming of PLCs [361]:

- Structured text (ST; IEC 1131/3) is particularly suitable for writing implementation-neutral specifications.
- The instruction list (IL; DIN 19 239, VDI 2880) is a low-level assembler-like PLC programming language (i.e., similar to machine language).
- With the ladder diagram (LD; DIN 19 239, VDI 2880), simulations of relay-based circuit diagrams are employed for PLC programming. This is a graphical language.
- The function block diagram (FBD; DIN 19 239, DIN 40 719, IEC 117-15) technique, another graphical language, uses elements similar to the circuit symbols for logic gates and memory elements in digi-

tal schematics (see Fig. 108). If individual logic and memory elements in the logic diagram are combined into macros ("actions" and "steps"; see Fig. 108), the result is a sequential function chart (SFC).

Figure 108. Linear step sequence
Macro representation: sequential function chart (left); Explicit representation (right) 1, 2, 3 steps; A, B, C transitions; X, Y, Z actions

– The sequential function chart (DIN 40 719/6, VDI 2880) is especially suitable for sequential controls where the individual control goes through states or steps not in an arbitrary sequence but (at least section-wise) in a fixed, linear sequence. This condition does usually hold in practice.

Besides these standardized languages, there are many manufacturer-specific languages, partially constructed from elements of the standardized languages (e.g., Siemens STEP-5).

Sequential function charts include not only sections of linear step sequences, but also branches. A distinction is made between OR (alternative) branches and AND (parallel) branches. In the latter, concurrent control sequences take place in the controller; that is, sequences that proceed in parallel and independently of one another until they are again synchronized to one another at the end of the AND branch. Such controls cannot be usefully diagrammed and analyzed with state diagrams; a much better tool for this purpose is offered by Petri nets [365]. The draft of DIN 40 719/60 for sequential function charts, in contrast to the old version of DIN 40 719/6, includes some important restrictions on branching options to permit Petri net modeling of concurrent controls.

Both Petri nets and sequential function charts are suitable for the specification, simulation, analysis, programming, operator interface, and documentation of controllers. They are particularly useful as support for hierarchical control concepts, which are often important in practice.

Classification of Control Systems. The common language of automation technology includes many control terms, most of which are defined in DIN 19 237 and many of which were mentioned in the preceding section. In what follows, these terms are listed under different classification criteria.

– Signal-oriented classification: analog, digital, binary control
– Function-oriented classification: combinatorial, sequential control
– Structure-oriented classification: asynchronous, synchronous control
– Technology-oriented classification: wired-program control, stored-program (programmable) control; (wired-program control:) fixed-programmed, reprogrammable; (stored-program control:) RAM-programmable, exchangeable memory; relay, contactor, electronic control; mechanical, hydraulic, pneumatic, fluidic control, etc.
– Hierarchy-oriented classification: individual, group, coordinating control
– Application-oriented classification: interlock control, sequence control; burner, scale, transport, recipe control, etc.

Another concept is mode control, which refers to a control level, higher than the signal-processing part of a sequential control, in which an operating mode is selected. VDI/VDE 3683 and DIN 19 237 define the following modes (among others): automatic, semiautomatic, single step, step setting, manual. In hierarchical control concepts, the operating modes available may differ from one level of the hierarchy to another and must be coordinated in a suitable way.

Figure 109. Actions as a means of plant control

4.5. Operational Control of Process Plants

Requirements on the operational control of process plants have grown much more stringent. The reasons include increasing flexibility in production, shortages in personnel and plant resources, shorter product throughput times, production structures with cross-links due to energy and product coupling, quality assurance standards, and the greater and greater number of maintenance operations that have to be performed at regular intervals. Optimized production programs and maintenance practices must be integrated into a plant control concept against the background of environmental and occupational safety and health requirements and the reliability standards that they imply.

A number of approaches have been devised and used with success for specific problems.

Brombacher [370] and Niese [371,372] used the term "process logistics" to describe proposals they developed for managing product streams given the coupling of process elements in normal operation, but also in transient and exceptional situations.

Under the leadership of NAMUR, "recipe" control concepts were developed for batch processes; these have been implemented as standard products by control system manufacturers [373].

Riemer has described concepts for production control, which have been turned into tools [374].

The same holds for special functions at the plant complex control level [375].

A closer analysis reveals that these concepts do accomplish their specific goals but are not consistent with one another in the sense of operational process control.

In future, accordingly, a broader approach must be taken to the operational control of process plants.

The action and resource model discussed here is one such expanded approach to describing the operational control of a process plant. The model is constructed in an object-oriented way. A wide variety of requirements, relating to recipe-based process control, logistical product management, maintenance, and other areas, can be reflected in the model.

The model includes a general formalism for resource allocation and control. Automated tools support the application of the formalism. In the context of the level model, the action model represents a logical standard interface between the production or plant complex level and the process control level.

Introduction. The fundamental task of operational process control is to coordinate and, with the aid of plant resources, carry out various

tasks stemming from production requirements, in-plant product logistics, or technical support and plant maintenance.

The action and resource model provides a formalism for systematically finding and implementing solutions.

The action model is based on the idea that every task arising in operational plant control can be completely accomplished by performing individual actions. These actions are performed through orders on the available resources.

The process control problem is thus broken down into three parts:

1) Mapping of tasks into individual actions
2) Planning and scheduling of these actions
3) Control and monitoring of the performance of the actions

Figure 109 illustrates the basic structure of the model.

Some important concepts figuring in the model are explained first. These should be understood as working concepts and are used here only in a very restricted sense.

Functional Units. A functional unit is, quite generally, a unit aggregated from various functional elements and, as a whole, accomplishing a self-contained task. Functional elements are selected such that they can be directly implemented with the help of existing plant equipment. Thus they are not fictitious functional objects but concretely represent the capability of a group of process devices. A plant complex includes a variety of functional units, such as plant sections, maintenance foreman groups, auto transport services, energy sources, and so forth.

In general, functional units are organized in a hierarchical manner (see Chap. 2).

Maintenance groups, for example, are organized as follows:

Maintenance technician
Maintenance gang
Maintenance foreman group
Maintenance support group

Process-oriented functional units might be organized as follows:

Individual functional unit
Group functional unit
Plant section unit
Plant unit
Plant complex

The internal structure of these units is discussed in depth below.

Resources. In the concept discussed here "resources" means "that which can perform services in the plant." Resources correspond to functional units that do not functionally overlap and which together represent the capability of the plant. Resources so defined are "intelligent" units to which the plant can pass on orders either directly or through plant actions. Resources are part of the permanent equipment of a plant complex; they are present whether they are processing an order or not. The sum of the resources reflects the functional capability of a plant complex.

Several special rules apply to resources:

– Self-sufficiency:
  Each resource has the capability of managing itself and independently carrying out orders. For the real performance of its task, each resource has its own apparatus and resources to which it has unrestricted access. Each resource can thus be planned, scheduled, and worked independently of all other resources.
– Control interface:
  Each resource has a control interface and an allocation mechanism associated with the interface. A resource may be needed for a variety of plant actions. At any time, however, only one action is allocated to a resource by means of orders. The planning and scheduling of resource utilization is accomplished by higher-level functions. Independently of such planning and scheduling, however, each resource has an allocation mechanism, which locally protects it against improperly being assigned more than one order.
– No parallel processing of orders:
  A specific feature of this model is that each resource can process only one order at any time. Accordingly, there is no concurrent working of orders within a resource. This provision is crucial in determining the overall structure of operational process control.

This "flatness" and the ban on parallel processing of orders are an important advantage

in making operational control easy to understand and simple to implement, but they represent a severe restriction on structuring. Functional units, as substantial objects, can be aggregated in accordance with the structural principle. The rules for resource formation now require that one level of aggregation be selected and permanently identified as the resource level used for operational process control. Only the functional units on this level are competent to perform operational process control services. If, for example, the maintenance foreman group is identified as the resource for the maintenance hierarchy, the operational process control system can then issue orders only to the foreman group. The issuance of an order to a gang or to a support group would not be permitted. In this example, the rules would demand that a foreman group be processing only one order at any time. This is, however, generally not so in practice. Accordingly, a foreman group is not the proper resource for operational process control. The resources identified should be those on a lower level of aggregation. Gangs, in general, process only one order at any time; hence gangs meet the criteria for a resource and would be a suitable choice as schedulable units for operational control of the maintenance area.

It is important to stress that this restriction to one level of aggregation relates solely to operational process control. All the levels of aggregation are still of interest from the standpoint of other organizational concerns.

Actions. The plant complex can accomplish its task by issuing orders directly to its resources. Such a manual procedure is, however, expensive for the plant complex and also hard to track. The action model offers a more convenient solution. An action is a self-contained control unit that permits the automatic performance of an entire functionally coherent block of tasks. Typical actions in this sense might be

- "Pump X liters from tank A to tank B,"
- "Do the scheduled maintenance on emergency trip system X,"
- or
- "Produce X tons of A in accordance with recipe B."

For each action there is a performance specification, which sets forth how the action is to be carried out. Any action may require more than one resource for its performance.

Actions can be combined and grouped at the plant complex control level. At the interface to the lower-order process control system, however, each action is essentially a self-sufficient, independent, self-contained object. The model says nothing about the complexity of an individual action. Both extremely complex actions and elementary actions can be defined and carried out simultaneously in a system. Actions need not be free of redundancy as to their functionality. For example, an action such as "transfer X liters from rail transport to tank A" may well have the same elements as the action "Pump X liters from tank B to tank A." Regardless of the nature of the task or the type of resources employed to accomplish it, a common scheme is used for performing and managing actions. In this way, they form an object class with well-defined properties. In the hierarchy, actions form a standard interface between requirements on plant management and operational performance. This formal decoupling is an essential goal of the action concept, but it should not be taken to imply that task and execution can be analyzed and organized independently of one another. If the structures of resources and those of tasks are not consistent, the result will be a poorly organized package of actions that cannot be efficiently carried out.

Thus it makes no sense, for example, to define special plant engineering resources simply for purposes of process control if such resources cannot be utilized to perform maintenance actions or contribute to in-plant product logistics.

Central importance attaches to the development of a resource structure that is matched (in substance and form) to the internal concerns of various task areas.

Requirements on Operational Plant Control. Operational plant control must meet requirements arising from many areas. These are broken down by the concerns of the areas where they originate. The next section presents examples of "Requirements from Production Planning," "Requirements from In-Plant Product Logistics," and "Requirements from Plant Support" in order to show how actions can be derived from requirements.

Requirements from Production Planning. From production planning, the plant complex re-

ceives orders to produce certain products, along with product-related specifications such as product name, nominal quantity, nominal quality, and nominal deadline. In order to accomplish this production, a number of actions must be initiated and carried to completion. These actions can be analyzed in two ways:

- An operational breakdown of the production process into steps corresponding to the subdivisions of the process
- A purely quantitative breakdown of the production process into lots making up the desired (nominal) quantity
- Operational breakdown of the production process

For structuring purposes, a production process can be broken down by using the phase model (see Chap. 2, Figs. 33, 34, 35, 36, 37, 38). Figure 110 shows an example for a process A. At the left, the entire process is shown as a closed block with inlet products IP1 to IP3 and outlet products OP1 and OP2. The guiding principle in breaking down the process is that the operations belonging to a process can be separated by simply dividing up the material system by product and dividing up each operation into phases by time.

If this is possible, individual, self-contained subprocesses corresponding to the phases of the phase model are obtained. Each subprocess is characterized by the performance of certain operations. In the example shown, these operations are reaction A1, separation A2, reaction A3, mixing A4, and reaction A5. The products at the beginning and end of a subprocess have well-defined properties. In the example, these products include the inlet and outlet products of the overall process plus intermediate products ZP1 to ZP4. The subprocesses are coupled to one another via these products.

Depending on the complexity of the overall process, the same scheme can be re-applied to break down the subprocesses.

This method reaches its limit when operations cannot be further separated either by a product-related subdivision of the material system or by a time subdivision into phases.

Production specifications are instructions for the execution of a production in a plant. In other words, they are performance specifications for production actions. They extend beyond general process descriptions, stating precise conditions to be maintained and states to be established in order to carry out a certain process in a plant.

These conditions include, for example, properties of products that enter the process. The starting material present in the plant at the beginning of a process should also be regarded as a product occurring in the process.

An important initial condition is the state of the plant at the beginning of the process (see also Section 2.3). Initial condition refers not only to state variables in the narrow sense, such as temperature or control state, but also to general properties such as "degree of contamination," "functional reserve," "modification effected," and so on. These conditions govern the need for tooling or cleaning orders.

The fundamental part of the production specification, however, describes how certain process properties must be controlled in the course of the process so that the desired overall process can be carried out. This also includes the establishment of certain intermediate and end product properties [376]. Each production specification is based on a model of a reproducible process.

By analogy to the breakdown of a process, a production specification can also be divided into parts (see Fig. 25). It should be noted that every portion of the specification, by virtue of the analysis, contains supplementary conditions on the inlet product (feed) properties and on the states of plant sections at the beginning of the subprocess.

When such a breakdown is carried out, a production specification becomes a number of subspecifications, each of which describes the execution of a subprocess in a plant section (see Fig. 26).

It is evident that the analysis of processes and production specifications has a direct effect on the structure of action objects and the way they are managed. This can be illustrated by two extreme situations as shown in Figure 111.

In Example 1, the process has not been broken into parts. In other words, the action takes in all partial production steps including intermediate product transport. The overall production process, including the time sequence, is described by a single production specification and, in its entirety, corresponds to a single action.

In Example 2, the overall process is divided into subprocesses, for each of which there is

Figure 110. Breakdown of a process in the phase model

Figure 111. Complex and simple actions
Z = prerequisites strictly state-oriented; A = prerequisites also sequence-oriented

a partial production specification independent of the other subprocesses. An independently schedulable action is assigned to each subprocess. Temporal coordination is achieved through the availability of intermediate products and the initial conditions for the individual subprocesses. Coordination comes under the planning

and scheduling functions of the production or plant complex control level.

What level of "granularity" is appropriate for a given production process will depend on the requirements and constraints imposed. The action concept permits arbitrarily broad or granular actions and does not place any restriction on the depth of the breakdown.

– Quantitative breakdown of the production process

If the nominal product quantity is too large to be produced in one step in a closed material system, the overall production can be subdivided into individual batches. A number of batches can be combined into a lot, and a number of lots into a campaign. The NAMUR definition states that a lot is "a delimitable and identifiable quantity of product having a uniform quality. In the case of a batch production process, a lot may include one or more batches" [373].

Again, the action concept allows any degree of aggregation. In general, actions will relate to the production of one batch; the combination into lots is a planning and scheduling task. In the extreme case, however, a complete lot can be defined as a single action.

Requirements from In-Plant Product Logistics. In-plant product logistics refers to the control of product (material) flow within the plant complex. This activity supplies inlet products (feeds) to the "producing" plant sections and removes the end products and byproducts. The tasks of in-plant product logistics also include the control of internal buffers, tank storage, bunkers, high-bay warehouses, and devices used for storage and reclaiming. This area of responsibility may also extend to the control of tank cars, rail cars, and other mobile storage located on-battery.

Depending on the application, product-logistics activities may take place in the context of production actions or may be independently planned and scheduled tasks executed by separate actions. Such actions might then be:

– "Transfer by pumping,"
– "Convey from tank X to tank Y,"
– "Transfer from tank car unloading station A to tank X,"
– or the like.

These actions are required to be highly flexible as to scheduling. Often the orders are not issued until shortly before performance, or rescheduling may be necessary at the last minute (e.g., tank cars are in the wrong sequence on the track, operators at the tank car terminal wish to carry out order A before order B, etc.). This required flexibility in the planning of logistic actions and the requirement that noncentral (local) entities must have access to scheduling (e.g., from the receiving station) must be taken into account in the design of the scheduling system.

For higher-level product management, the granular logistic elements are combined into more complex units. For example, starting products may be delivered to the plant complex, whereby each delivery may consist of a number of tank cars. Within the plant complex, not the receipt of the delivery as a whole but rather the discharge of an individual tank car is generally regarded as a single action. Again, however, the action concept is open and permits modification to suit the organizational setup of the plant. (For example, a complete coal train is unloaded in a different way from a delivery made up of separately marshalled cars.)

Requirements from Plant Support. Plant support, in order to accomplish its tasks, must periodically carry out plant inspection, maintenance, and repair operations. These can also be defined and performed as actions, for example:

– "Calibrate probe X,"
– "Drain separator sump,"
– "Do scheduled maintenance on pump A,"
– "Inspect overcharging protection B,"
– and so forth.

If a maintenance action renders plant equipment unavailable for production while the action is being performed, the maintenance action must be included in the planning and scheduling system like any production action. The action concept permits a systematic treatment of maintenance actions in resource allocation. What is more, it allows plant-wide monitoring of the progress of planned maintenance. Every maintenance operation defined as an action in the system monitors its own correct performance. If unplanned events occur, the progress status of the action should reflect them. If necessary, an explicit notification should be provided to plant management or the planning and scheduling system (see Fig. 20).

Maintenance operations can be broken down in two ways: (1) by the functions or functional units maintained and (2) by expected frequency, for example, on a time or wear basis. Ultimately, these analyses lead to individual activity elements. Job planning combines these elements into packages meaningful from the engineering, functional, and management standpoints, and the packages are treated as maintenance actions for planning, scheduling, and administrative purposes. How this grouping of elements takes place in a particular case will depend in the maintenance concept practiced at the plant complex (see Section 11.4).

Analysis of Plant Equipment and Definition of Resource Structure. The plant complex has technical equipment and personnel resources at its disposal to perform its tasks. This section describes how the apparatus and personnel resources can be broken down and how they can be combined into technologically meaningful functional units. On the basis of the system of functional units created in this way, a suitable resource structure can then be established.

This description is for the example of plant engineering functional units but can be extended to other areas as well.

Breakdown of Plant Equipment. The purpose of analyzing equipment and apparatus available in the plant complex is to identify clearly delimited, nonoverlapping elements. Elements belonging to various devices can then be assembled into meaningful functional units. The process is illustrated for the combination of plant equipment elements and control system elements into plant engineering functional units.

– Breakdown of Process Equipment
  Production takes place in process equipment and facilities where the product is conveyed, stored, and transformed. A process plant or facility ultimately consists of valves, pumps, pipes, and so on. Between the plant as a whole and these single elements, however, a number of useful analytical levels can also be found. An important level is the plant section. From some points of view, the plant section is actually more important than the plant. Plant sections are typically delimited in such a way that further subdivision of the material system present in them is impossible or needless. Thus exactly one subprocess can run in a self-sufficient way within every plant section. Here "exactly" means that one, but only one, subprocess can take place in any plant section at a given time.
  A plant section has inlets where products enter it and outlets where products leave it. These inlets and outlets serve to connect plant sections to one another. The topological structure implies certain rules for product streams between plant sections. Figure 112 shows the most important basic ways of connecting plant sections. In the train, a product moves through one plant section after another (stage by stage). If there are several trains, a product moves through only one of the trains. In present-day chemical plants, especially plants where several different products are made, these structures are no longer found in pure form. Instead, the plant sections are connected by a complicated network of piping. Figure 113 gives an example of such a complex structure. A plant section consists of the components exclusively assigned to it, such as valves, pumps, sensors, piping connections, and so on.
  Within a plant section these components can be assembled into groups. In general, a group has the property that it effects a certain flow of matter or energy in the plant section. Figure 114 shows a reactor with its groups.
  Each group consists of the components exclusively assigned to it.
  Groups are coupled to one another by transfer points for matter or energy, called connections.
– Breakdown of Process Control
  The goal of process control is to bring about certain process properties. A certain control logic is required for this purpose. The basic structure of this control logic is described by a control model.
  The basis for the control model employed here is a hierarchical control model. As Figure 115 shows, a control unit receives orders, commands, and setpoints from a higher-level unit. It executes the order by, in turn, specifying orders, control values, control parameters, and commands to lower-order control units. How it does this is an aspect of its internal logic. The methods of feedforward and feedback control can be used to derive a suitable internal logic.

Figure 112. Basic connection patterns of plant sections

Figure 113. Real network of connections between plant sections

Grouping of Functional Units. The purpose of forming functional groups is to combine plant equipment in various areas in such a way that it together accomplishes a partial task of the plant. Workable modules for accomplishing the overall task of the plant are obtained in this manner. This is illustrated by an example of the grouping of plant units and control units.

Plant (equipment) units and control units can be combined into functional units. The model provides that one control unit is assigned to each plant unit.

At the lowest level, for example, individual control elements such as valves, pumps, electrical heating devices, and so forth, are grouped with individual control units to form "individual functional units." Such an individual functional unit for the blocking and release of a product stream is illustrated in Figure 116.

Each individual functional unit permits a certain process property to be set (see also Section 6.2).

The second level comprises group functional units. Figure 117 shows schematically how a group functional unit is built up. A group func-

Figure 114. Groups of a reactor

Figure 115. Hierarchical control model

tional unit consists of a group of individual functional units exclusively assigned to it, together with a group control unit, which controls and coordinates the activities of the individual functional units.

The overall goal of a group functional unit is to combine a group of individual functional units from the control standpoint in such a way that together they act on the process in a manner that is meaningful from the process engineering viewpoint. Individual effects that do not add up

to an effect meaningful in terms of process engineering are excluded by the group functional unit.

Figure 116. Structure of an individual functional unit

If several effects useful from the process engineering standpoint can be brought about with a group of individual functional units, the group control unit supports each of these effects with its own control structure. The group functional unit is said to have alternative or selectable "modes."

The functionality of the group functional unit is implemented when the group control unit issues specifications to its assigned individual control units in accordance with the control model.

Figure 118 illustrates the structure of a group control unit.

Note that the group functional units discussed here have also been described under the name "basic functions" [377, 378]. Because this term leads to repeated misunderstandings, however, and has been under discussion in NAMUR [373], it is not employed here.

The third level is that of plant section functional units. A plant section functional unit consists of the group functional units of the plant section and a plant section control unit. The plant section control unit reflects all the process control capabilities of the plant section. Typically, group functional units permit an arbitrary number of meaningful program options. Which option is needed in a particular case is set forth in the performance order for the individual process. In this way, when issuing an order to the plant

Figure 117. Structure of a group functional unit

Figure 118. Structure of a group control unit

section control unit, it is necessary to provide not only control values, control parameters, and commands, but also portions of the performance specification.

To sum up:

Each level offers certain possibilities for functional intervention in the process; that is, each level can carry out certain process control orders. Furthermore, each level completely reflects the process control capability of the plant.

The higher the level, the more complex the task. In the simplest case, the order is to open or close a valve or to set a certain flow rate.

Every functional unit contains control units that carry out specific tasks. A control unit receives orders and/or control values from a control unit on the next higher level and, in turn, issues orders and/or control values as setpoints to control units on the next lower level. The number of levels in the hierarchy can be selected on technological grounds. Criteria might be, for example, the size and complexity of the process plant or facility. For the reference model under consideration here, a two-level structure below the plant section is chosen.

Determination of a Suitable Resource Structure. Establishing a suitable resource structure means selecting an appropriate set from the many functional units for operational plant control. The following criteria must be taken into account:

- The set chosen must fully cover the plant properties relevant to operational plant control.
- The functional units in the chosen set must not overlap. No resource may contain devices belonging to another resource.
- The structure of the resources must have a modularity suitable to the requirements.

Figure 119. Control hierarchy

Figure 120. From performance specification to implementation

In what follows, possible resource structures are discussed for the example of plant functional units.

The criteria of completeness and freedom from overlaps are satisfied at the levels of individual functional units, group functional units, and plant section functional units.

Accordingly, the level most suitable for analysis can be selected.

Maximum flexibility is gained by selecting individual functional units as resources, though at the cost of involved performance specifications. The fact that there are group control functions, which can coordinate the individual functional units independently of the action being carried out, is not included in the treatment. The coordination of individual functional units must be explicitly described in each concrete case by means of instructions contained in the performance specifications for the action.

If group functional units are chosen as resources, virtually all the order-neutral conditions and program steps are contained in the internal logic of the resources. Simple and powerful performance specifications result. Group functional units are an appropriate choice. In the model

under consideration, group functional units are identified as plant engineering resources. In this way, every order involved in operational process control references one group functional unit. Orders to individual functional groups are no longer possible. Plant sections are not known to the operational plant control system, and there are no plant section control units.

Figure 119 shows the control hierarchy that results from identifying group functional units as resources.

In some process control concepts in use at present, plant section functional units instead of group functional units are the resources for allocation, planning, and scheduling. This notion is suggested by the rule: "At any time, only one subprocess can take place in a plant section." In practice, however, this approach results in some difficulties and disadvantages. Such problems arise, for example, in managing the interconnection of plant sections. Other difficulties come about when actions in the areas of in-plant product logistics or plant support are considered; here it is a hindrance to assume that one, and only one, action can be performed in a plant section at any time. For example, given certain constraints it is quite possible that production, calibration, and maintenance actions can be carried out simultaneously in a plant section.

A component-oriented control structure leads to further difficulties as well. In multifunction facilities, plant sections often carry out many different subprocesses. The needed control specifications can no longer all be established as "modes" embodying all the capabilities of the plant. They must be loaded into the plant section control systems before the subprocesses are performed. This procedure of loading program sections into existing control units entails serious conceptual problems.

On the whole, there is no advantage in the functional coupling of group functional units to form plant section functional units that can be allocated. The reference model accordingly looks directly to group functional units as the allocatable plant engineering resources.

Regardless of the resource structure, the plant section naturally plays a major, if not the central, role as the smallest unit of the plant engineering world.

Consequences of the Choice of Resources. The selection of a functional unit as resource not only implies additional formal requirements on the functional unit itself, but also has a strong effect on the semantics of the performance specifications for actions and on the overall structure of the plant control system. These consequences must be considered when making the choice.

Additional Formal Requirements. Resources in this model are self-sufficient, largely self-managing, and self-protecting objects. All resources must exhibit certain standard properties. In this way, the issuance of an order to a resource is standardized and is formally independent of the type of resource. An order to a maintenance gang does not differ formally from the order "heat" given to a group functional unit.

The formal provisions include the following standard properties of a resource:

Standard order interface. Each resource must have an interface through which it can receive orders, setpoint values, control parameters, and so forth. The interface is standardized and is, formally, the same for all resources. It is dedicated to communications with the allocating customer (e.g., action X, action Y, manual intervention).

Standard status interface. Each resource must have an interface at which it makes certain (generally standardized) significant states available as information for other units. This interface provides information to all interest units and is held available by the resource as a read-only interface. It is formally standardized and is the same for all resources. The value ranges of the state variables "availability state," "type of allocation," and "operating state" are consistent for all types of resources.

Allocation logic. Each resource protects itself against multiple allocations. The allocation logic uses a simple principle: The first to allocate an available resource is the customer. A customer must release the resource in order to make it available to other potential customers. Prioritization and the identification of optimal allocation sequences are in the planning and scheduling domain; these operations are not supported by the resource itself. This simple structure appears to be especially appropriate for process engineering, where briefly interrupting one production process to make the resource used for it available for another task is generally not desirable.

Self-management and self-organized activity. Each resource is a functional unit that manages itself and operates in a manner internally independent of an allocating customer. Even unallocated resources carry out their control tasks and are continuously active and operational. Resources are responsible for the correct functioning of the equipment subordinate to them and the management of their resources. They are intelligent alarm and report generators.
Self-sufficient protective logic. Each resource has protective logic to prevent its creating a forbidden condition. This protective logic operates under its own rules, independently of the order system, and insures priority local protection.

Semantics of Performance Specifications. Once the resources have been chosen, the reference elements are identified for the formulation of actions. The selection of resources thus influences the way of thinking and communicating during operation. The importance of this fact is commonly underestimated when specialists analyze their individual areas.

The linguistic consequences can be illustrated for plant engineering resources.

Three examples of plant engineering resources are considered.

If the input/output channel is chosen as the resource, the performance specification will contain elements such as "set output BA43," "read input AE65," and so forth.

But then both the EMR/process control system engineer who writes an automation function and the chemist who formulates a recipe must ultimately do so on this linguistic level.

It is obvious that this "channel level" is unsuitable as a medium of description.

If individual functional units are selected as resources, the requirements can be formulated in engineering language. The performance specifications now contain elements such as "pump 34 on," "valve 56 closed," "setpoint for controller 36 = 50 °C," and the like. Accordingly, this level permits an engineering formulation and includes device-specific details. But the formulation depends on the specific instrumentation present in the plant.

Finally, if the group functional units are chosen as resources, the instrumentation-related details become internal to the resources. Group functional units represent the functionality of plant (equipment) units. Now the performance specifications will contain elements such as "heat to 40 °C" (vessel heating), "meter in 100 L at 1 L/s" (inlet line), "mix vessel contents" (stirrer), and "transfer up to a maximum of 300 L" (inlet line). In order to avoid terminological confusion, Figure 120 shows the situation schematically. The focus is on the "performance order," which corresponds to a concrete instruction to a group functional unit to perform a certain procedure. Every group functional unit has the capability of doing certain procedures. On the other side are the possible performance orders, that is, the linguistic elements from which the performance specifications are assembled.

Group functional units are a convenient, meaningful, and workable level. Choosing this level permits both the formulation of performance specifications for automatic actions and the manual control of actions by issuing single performance orders at a technologically understandable, not excessively complicated level.

Actions. Each action serves to accomplish a self-contained partial task and, within the plant complex, is a separate, identifiable object. How an action is to be carried out is set forth in its performance specification. The system responsible for the performance of an action is identified in planning and scheduling. This performing system must know the performance specification or must be given it. For example, the processing of a production action can be transferred to the plant operator or the process control system. If the action is assigned to the process control system, this system independently performs the action in accordance with the performance specification stored in the system. If the action is assigned to the plant operator, the operator handles the action by manually issuing performance orders in accordance with the performance specification contained in the operating manual. Processing includes issuing performance orders, controlling the allocated resource, collecting archival data, generating the proper reports, giving the ready signal, and monitoring correct operation.

Each action is generated, planned, and scheduled by the plant planning entity and is transferred to a performance system where it is actively processed. It is then deleted from the performance system and the planning and scheduling system, remaining only in the archive sys-

tem. Figure 121 shows the states of an action and the possible transitions.

Figure 121. Operating states of an action

Lot planning, tank storage planning, maintenance planning, and other activities generate requirements for the performance of certain actions in certain spans of time. In order to schedule the performance of these actions, all actions planned up to a certain time "horizon" are reported to the in-plant planning and scheduling entity. An action thus becomes an object in the planning and scheduling system, which maintains a list of all actions generated. It makes available an operator interface, with whose aid further actions can be generated and existing actions can be rescheduled, modified, and deleted if necessary. The planning and scheduling system supports planning by means of prospective calculations, then uses the list of actions to be performed together with the current status to arrive at resource allocations, determine the contents of product storage units, and predict the future states of the actions.

For this purpose, there is a simulation specification for each type of action. With the help of this specification, which treats each action as a planning and scheduling unit, it is possible to forecase when which plant resource will be needed, and to say when and where substances are to be received and discharged (and in what quantities).

On the basis of such a forecast, the action plan can easily be checked for critical resource allocations or critical states of product storage units.

During production, this forecast must take account of the actions now running and those loaded. In other words, the planning and scheduling system must always know the present status of all actions being processed.

Scheduled actions are initially pure scheduling objects in the planning and scheduling system. At this point, they have no access to resources. To be performed, actions must first be loaded. When an action is loaded, a performance system is ordered to perform it; this system receives all the required functions. If there is no instruction to the contrary, the performance system then automatically carries out the action.

An important property of the loading operation is that pre-loading is possible, meaning that an action can be loaded into the performance system long before its scheduled performance. In this way, the requirements on the availability of the planning and scheduling system are eased. An adequate reserve of actions can always be kept loaded in the performance systems. For example, all production actions to be performed automatically in the next 24 h can be loaded into the process control system; the maintenance group is given a list of all maintenance actions to be carried out for the week; the plant operator receives a list of all production actions to be performed manually during the weekend.

A performance system of special interest for process control engineering is the process control system. The loading and automatic execution of actions might be thought of in this way: When an action is loaded, a control unit is created in the process control system and initialized.

The control unit is a self-contained object with the ability to verify conditions and to perform its task automatically. It is no longer dependent on the intervention of higher levels but still can, if necessary, be influenced by higher levels. The loading of an action can be initiated either manually by the plant operator or automatically by the planning and scheduling system.

Figure 122. The action as control unit

Once loaded, the action considered as a control unit goes into an initialized condition: "loaded, waiting for start." It has no effect on process control and no access to resources, and it can be deleted or reset at any time without having exerted any influence on the system. The processing of the action begins when the control unit is started; during this operation, the control unit is given access to the needed resources. It gains such access through allocation of group functional units and the construction of the control links required for this purpose. Two concepts should be distinguished here. In the simpler one, all links that the action will need at any time during processing are made at the outset. In a somewhat more complicated concept, only those links called for during the initial phase of processing are present at any time; links that are no longer needed are dynamically broken while the action is still being processed.

Once an action is complete, all links created for it are abolished.

While an action is being processed, the action control unit acts like a normal, permanent control unit (Fig. 122).

Once an action has left its initialized state and has been started, it cannot return to the initialized state. The action has been launched, cannot be called back, and must be processed all the way to a correct or incorrect termination. Every action, once started, is stored in an archival system; it cannot be cancelled without entry in the archive. All stored information about the progress of the action and all stored information about group and individual functional units working under its control can be accessed by virtue of this entry in the archival system.

The form of storage depends on the implementation.

It is evident that the action model described here is especially suitable for batch processes, where a one-to-one mapping of actions to production actions is possible. The steps in an action (see the state model in Fig. 121) largely correspond to the steps in a segment of a batch production process.

This is not the case in continuous processes, which are characterized by the continuous operation of process steps rather than by steps with definite terminations. The stress is on managing and controlling the modes and transitions between modes as shown in Figure 123.

Nonetheless, continuous processes can be described in terms of the action model. One simple option is to "discretize" the continuous process into small increments delimited in time and having definite production objectives.

Automatic Performance of Actions. The automatic performance of actions means implementing the functions required to complete the action by using automatically functioning software or hardware modules. This can be achieved, for example, by implementation in a process monitoring and control system, a maintenance system, or another system for carrying out actions.

The reference model has a structure appropriate for this purpose: Resources and the actions themselves are built up in object-oriented fashion, in two senses: first, that each resource or ac-

Figure 123. Operating modes of a segment of a continuous process [370]

tion contains its own control unit and thus acts as a self-contained unit in the system; second, that the resource or action has properties that can be derived from a type concept. Control units occupy places in a control hierarchy. Each control unit is connected to the next higher-level control unit and the next lower-level control units through well-defined control interfaces. In addition, each control unit has interfaces through which it can exchange information with all other units.

In process control systems, control units can be implemented as modules. This is a common and a standardized practice in process control engineering; for example, the IEC standardized languages (WG65A) are based on an object-oriented modular approach.

Example of a Modular Solution. The following section shows how the action and resource model can be implemented in a modular form in a process control system. The modular model has the following properties:

– *Support of the type concept*
  The type concept is a special manifestation of a one-level abstraction hierarchy. Each module is of a certain type. The type defines all methods, the description of connectors (input/output interface module), and the description of internal variables. Further, the type includes certain type-specific variable values. The entity, as a management unit, contains not only its name but also its specific data set and the reference to its type. Accordingly, the entity contains no methods or variable descriptions, only parameters.
  In contrast to the individual device approach, in which each compact controller contains the type information (e.g., control algorithm), in process control systems the type in-formation can be contained only once, in one component. Entities then contain only the module state information and module-specific parameters. Under this concept, the type information must already be present in the target system before the creation of an entity. Loading of type information is a separate step from instantiation of the individual module.
– *Data exchange through connectors and links*
  According to this concept [379], data exchange between modules must obey the following principle: Every module offers certain connectors to serve as interfaces to the external world. Two matching connectors of two modules are connected to each other via a link. Once the link is in existence, data can be exchanged. The construction of the link itself is a separate process from data exchange. Links are independent management objects in the system and can be created and again destroyed while production is under way.

Figure 124. Separate loading of performance specification and action (performance system here = process control system)

– *Closure of modules*
  Each module as a whole is a unit that can be manipulated. Modules are created by simple instantiation commands. The prerequisite is that the proper type must be present. Once modules have been created, they can be incorporated in the processing by an activation command. They bring along all the prerequisites for their function. Modules can be created at any time, and also deleted again, while production is under way. Once modules have been deleted, no fragments remain in the system.

A particularly simple implementation of the action concept is obtained if all functions required for the performance of the action are contained in the performance specifications (and thus in the type description). The individual action contains not specific functions but only parameters for the control of the performance specification. In this way, there is a strict division between the creation and loading of performance specifications, on the one hand, and the creation and processing of individual actions, on the other (Fig. 124). This strict separation is not a practical drawback, since in general the creation of performance specifications takes place separately from the scheduling and operational performance of the actions. The various tasks are often accomplished on different levels: Performance specifications are created and managed in a "recipe" system, while action management and initiation take place in a scheduling system.

An important performance feature of a process control system is how convenient it is to create and load a new performance specification, modify an existing performance specification, or generate the associated simulation specifications, original data sets, and parameter masks for actions being created.

Another important point, however, is that it is possible to attribute all required manipulations in the performance system to operations formulated in the modular concept. Thus no loading, writing, or coupling steps on the modular system are necessary. In this way, the action concept can be logically implemented in a modular system.

Automation. A very important property of the model is that automatically performed actions and actions manually performed by the plant operator can be handled concurrently in a process control system. It is thus possible to build up to a higher level of automation in a step-by-step fashion.

When actions can be automatically completed, a system acquires the degree of automation that Polke has called "logistical mode" (see Section 11.1) [376].

Summary and Outlook. The action and resource model attempts to describe a general structure of operational plant control. Important features of the model are the resource structure, the standardization of the order interface, and the introduction of "actions" as self-contained control and management objects. This contribution has taken the example of plant engineering resources in order to show how such a structure can be created and implemented in a suitable way.

The concept suggested is, however, a technology-free general mechanism. It is strictly limited to describing the operational performance of actions; thus it contains no specifications on how the planning and scheduling task is to be accomplished or on how recipes are to be generated, and it provides no rules as to how resources are to be selected and organized.

Special models are required for these purposes. By way of example, a resource model for plant engineering resources is described and its consequences explored.

A plant complex must carry out its tasks while fulfilling a variety of requirements and satisfying a number of constraints. "Plant-wide" decisions are needed on a daily basis. The action and resource model enables the plant to formulate its operational decisions in a consistent way and implement them in a systematic manner. The results are not just a simplification of scheduling, but also an improvement in the quality of planning and performance of in-plant actions. The documentation of plant activities is part of the concept and can be synthesized in a systematic way.

The action and resource model is logically object-oriented. It can be extended directly to a corresponding modular system.

With regard to usability, this model has the great advantage that technical devices and personnel can both be used in constructing resources and performance systems. Plants can thus be controlled in a consistent way, regardless of their instantaneous degree of automation.

A special task for the future is to integrate existing process control concepts for production control, plant management, recipe-based process control, and production logistics into the general methodology of the action and resource model, thus arriving at a comprehensive solution for the operational control of process plants.

5. The Process Control System and Its Elements: Process Sensor Systems

5.1. Principles

Sensor, Sensor Technology, and Sensor System: Classification and Standards. Modern process control engineering, with a distributed structure of information processing based on microelectronic devices, has greatly expanded the potential of the information economy for the control, monitoring, optimization, and reliable conduct of processes [380].

If this increasing potential of information processing is to be utilized fully, the amount of information acquired directly or indirectly as to the status of the process must also be augmented.

A relative bottleneck exists here, because the development of sensor technology lags behind that of information processing [380].

There are a number of reasons for this. Technical functional units in the immediate vicinity of the process are always much more expensive and complicated than those in a protected environment such as the control room. Furthermore, the continued use of conventional, internationally standardized signals together with proven transducer technology stands is hindering further development. Finally, information processing is often regarded as being much more important than information acquisition.

Decentralized process automation is beginning to extend distributed "intelligence" based on the use of microelectronics to the point where measurements are acquired. Therefore, the meanings of "sensor element," "sensor," "sensor technology," "sensor system," and "direct signal processing" have become blurred.

For example, consider the "critical" link in the action chain associated with measurement. In the current language of process and production engineering, the functional element that embodies the interaction between the material system and the instrumentation is referred to as a "sensor" [381].

Here, "sensor" no longer means the same thing as it commonly does in the electronics industry, where it is restricted to the proportional transformation of nonelectrical input quantities to electrical output signals [382, 383]. The appli-

cable standard (DIN 19 226) is therefore in need of revision. A useful starting point for a meaningful definition of the term "sensor" is offered by Sheet 3, "Apparatus Terms," of VDI/VDE Guideline 2600, "Metrology" [384]. This document employs "pickup" or "primary element" for the (entire) device that accepts the quantity for measurement at its input and emits a corresponding measurement signal at its output. The "sensor" proper, on the other hand, is the part of the pickup that directly acquires the quantity for measurement and reacts in some sensitive fashion to the quantity. Even this definition, however, is appropriate only for a relatively small fraction of the sensors currently utilized for measuring material quantities. The definition does apply, for example, to semiconductors and piezoelectric sensors; it is difficult to apply to IR photometers and paramagnetic oxygen sensors, because here the interaction between the material system and the instrument does not take place in the sensor, as VDI/VDE 2600 presumes, but via an energy field serving as an auxiliary quantity [385].

The present terminology and standards, such as the definition in VDI/VDE 2600, are thus insufficient and require further discussion. An unambiguous resolution of terminology in this area is essential in the long term.

Suggestions for refinement of the terminology have been made in [381, 383, 385, 386].

Here, it is proposed to separate information acquisition in and on the process from information acquisition in the laboratory and, as applicable, in the pilot plant. Both classical "process measurement" [387, 388] and "process analytical techniques" [389] must fulfill fundamentally different requirements from the comparable instruments in the laboratory. The shift from information acquisition in the plant laboratory and "process analysis rooms" to acquisition in the production process itself justifies the information-oriented term "process sensor system technology" as opposed to "laboratory measurement technology."

Process Models and Sensor Systems. The concept of "process model" has been known theoretically since the 1960s; it encompasses "black box," mathematical, physical, and other types of models. Especially important in connection with measurement technology are adaptive process models, also known as observer models.

Hundreds of books and tens of thousands of other publications have appeared on "process models" (see also Chapter 3), "process identification," and "process simulation." There are academic departments concerned with these topics, and many congresses and symposia on them are held every year. Although the theory is advanced, there is a wide gap between theory and practice [380, 390].

According to Perne and Polke [391], the process model is ultimately a mapping between product properties and process properties.

Problems of product variation or product development could thus be attributed to a process variation if a suitable process model were available. Identifying such a variation would provide a starting point for "optimization" under a wide range of criteria (see Section 11.3).

This problem can be handled systematically and – most importantly – optimized only if a representative mapping or transformation (i.e., the process model) can be found between the process space and the product space (see Fig. 408).

But why use a model instead of the real production process? Simply because the real process is generally much too complex and opaque to permit direct operations based on physical and chemical relationships and algorithmic descriptions of these (see Chapter 3).

However, this chapter is less concerned with the representability of a model in relation to the real process and the desired product qualitites, and more interested in the reaction on sensor elements and sensor system technology.

It is important, above all, that questions of sensor technology not be separated from the topics of process models, process properties, and product properties.

Material Flow, Energy Flow, Information Flow, and Sensor System. As Figure 125 shows, there is a prallelism and correlation between material – energy flow and information flow. The link between an event or state in the process and the information system is effected by the sensor system.

Accordingly, the sensor system has to carry out two basic tasks. First, the input quantity resulting from an event or state must be sensed and transformed into a signal quantity suitable

Figure 125. Position of sensor systems relative to material, energy, and information streams

for processing. Second, the signal quantity must be set in relation to its cause so that interpretation can extract usable information (see also Section 5.2).

The sensor itself must perform the first task, while the second is in the realm of information processing. Some thought should also be given to the possibility of augmenting the information by serial, parallel, or associative linking of single items, whereby the result may be of far greater relevance than the sum of the individual pieces of information. Typical examples are the temperature profile, the stress tensor, the density field, and the concentration gradient.

This multi-sensor approach is widely used in the field of biological sensors. A typical example for the capabilities of an array of identical sensors is image recognition by the eye. A further advantage of arrays becomes apparent in biological sensors but has been little utilized in industrial sensors: While the individucal biological sensor is markedly inferior in performance to many industrial sensors, a system with intelligent preprocessing of signals achieves an amazing degree of flexibility in dealing with unforeseen events. Naturally, this flexibility is more vital to biological systems than to industrial ones, where the service loads can be established more precisely. Nonetheless, the gain in flexibility through multi-sensor technology is of interest for industrial systems as well [392].

What holds for any economic system also applies to the information economy [393]: One can use only what one has. The first step, accordingly, must be information acquisition. It is reasonable to limit the information acquired to that which is important and actually necessary. There are two reasons for such a restriction: to avoid an information flood and to hold the cost of instrumentation within acceptable bounds. Both experience and mathematical and physical methods can be used as guides for limiting the information flow.

Because it is often difficult to identify the relevant properties, that is, the properties that adequately describe the process or the product, more easily measurable properties (indicators) are often resorted to. Process optimization requires better penetration into the process, and this in turn means finding ways to make relevant properties – i.e., those that can serve as significant process indicators – more measurable.

Hesse, in his editorial in the "Sensors 1992" special issue [394], used the following terms to describe the shift in emphasis in the development of sensor systems:

"At the beginning of the 1980s, the problems were to systemize technical terminology, to discover effects and technologies that could be exploited in practice, and to find out how medium-sized companies could establish themselves in this field. Later, in the mid-1980s, publications on practical sensors utilizing a wide

Figure 126. Assignment of attributes in the phase model of production [395]

range of technical principles became dominant. These were still in the foreground in the early 1990s, but systems aspects are now being examined along with applications and on an equal footing.

In fact, systems concepts should have been considered right from the start. These aspects aid in the development of strategic insights and objects, since they describe the overall high-level solution. The introduction of process control engineering in the chemical industry can serve as a model: Sensors are dictated by the system itself and can thus be developed under explicit constraints."

For these reasons, some concepts having to do with the use of sensor (system) technology in process control engineering are discussed first.

From Phase Model of Production to Process Information Model (see Chapter 2). A key aid in describing and analyzing processes is the phase model of production. This object-oriented semantic tool originated in software engineering. The outcome, a directed bipartite graph, belongs first to the category of product nets (see Chapter 2).

The phase model of production consists of two object classes, "product" and "process element." Individual products and process elements are described in terms of attributes. The attributes are the object classes of information about a process; they are defined by category and value (Fig. 126 [395]).

The value is made up of a numerical value and a unit. Whenever metric scaling is possible (see Chapter 3), the units employed should comply with U.I.P. 20 (1978) [396] and ISO 31/0 ("General Principles Concerning Qualities, Units and Symbols") and DIN 1313 [397].

Higher-level requirements such as "product quality," "process safety," and so forth are imposed on the production process.

Objective: Product Quality. Product quality refers to a subset of the actual properties of a product, which in terms of category and value form an intersection with the nominal properties demanded by the customer (Fig. 127). The development objective is to maximize this intersection within reasonable tolerances.

Figure 127. Product quality [398]

Ojective: Process Safety and Environmental Safety. Safety tasks such as process safety and environmental safety can be accomplished with the resources of process engineering and process control engineering. This can be achieved by means of technical or organizational actions [399] or a combination thereof (see DIN V 19 250 [400]). This procedure makes it possible to find alternative solutions that are equivalent from the safety standpoint, so that the most economical solution can be applied in imple-

mentation [401]. In the new NAMUR Recommendation, the required process control safeguards are matched to the risk arising from a process facility or the absence of such process control safeguards. This risk assessment is necessarily qualitative and must be carried out case by case. Other procedures that lead to a comparable level of safety should, however, not be ruled out. The protective objective in the context of this recommendation is to prevent injury to persons as well as major environmental harm and damage to property. In the case of major damage to property, damage assessed as serious danger (e.g., according to [402]) should be distinguished from damage evaluated as affecting the company's interests.

Figure 128. Safety, risk, and danger [403]

Some important concepts should be defined here (see Fig. 128), without an in-depth examination of the extensive safety literature [401, 403–405] or a workshop on Safety in Chemical Production:

- Danger: A danger is a situation in which the risk exceeds the limiting risk.
- Limiting risk: The limiting risk is the highest still-acceptable risk of a certain technical process or state. In general, the limiting risk cannot be quantified; it is described indirectly or in terms of safety considerations.
- Risk: The risk associated with a particular technical process or state is described in terms of probabilities. Two factors are included: the expected frequency of occurrence of an event leading to damage and the extent of damage expected when the event does occur.
- Safeguards are actions taken to reduce risk by lowering the frequency of occurrence, the extent of damage, or both.
- Safety is a situation in which the risk is lower than the limiting risk.
- Availability: The availability of a technical device is the probability that the proper functionality is present.

It follows that, with regard to the safety-related availability of process control devices, solutions for holding the risk less than the limiting risk should be evaluated from the economic standpoint only if they are equivalent from the safety standpoint.

In contrast, it is useful and necessary to analyze other availability characteristics to determine the economic consequences of malfunctions. This statement applies to the logistical availability of equipment that would impair the ability to deliver (just-in-time, just-in-case) and also to the process availability of production equipment that would impact directly on product quality or plant condition (e.g., production stoppages, market losses, repair costs).

The unambiguous description of proper functioning, that is, the complete set of all nominal attributes needed for such a description, leads to the information model of quality (Fig. 36) or the information model of safety (Fig. 37). The histograms illustrated show, for each product object or process object, all attributes necessary for its description, along with the nominal values and their tolerances ("good," "defective, acceptable," and "defective, unacceptable" ranges), which may be scaled either metrically or topologically (see Chapter 3).

This information must be statically and dynamically defined at the maximum level of detail [395]. What is more, the spatial and temporal representativeness of the attribute values must be taken into account, especially for ex-line sensor systems (Figs. 144 and 145).

Product and Process Properties. The attributes used to describe the objects of the production process are process properties and product properties.

The term process properties includes the following:

- State variables, such as pressure, temperature, and concentration, with which the process can be described either directly or via derived state functions.

– Process parameters, such as heat-transfer coefficient and catalyst activity, which characterize the constraints under which the process takes place. Process parameters are steady or at least quasi-steady quantities.
– Controlled variables, such as motor speed and setpoints, which characterize actions on the process.

In theory, the process can be described completely if a suitable set of these quantities is available. In practice, however, it often happens that not all the desired state variables and controlled variables can be measured or specified. Substitute information often must be resorted to:

Setpoints, such as stirrer speed, are correlated with the controlled variables or represent residual categories.

Process indicators [406] are empirically correlated with one or more state variables (and may also be product properties; see Section 11.3). These represent substitute information.

Controlled variables and setpoints characterize the part of the process state that is imposed from outside. It is the task of the actuator system to convert the specification, provided by the information flow, to an action on the process. The remaining process properties characterize information that is to be acquired from the process with the aid of sensor technology.

Product properties are the following:

– Physical quantities
– Chemical quantities
– Technological properties [406]
– Product indicators (see above), which are substitute information

Technological properties are determined by special inspection procedures when relevant product properties depend on physical quantities that can be determined only with great difficulty, or if the relationship with the physical quantities is currently unknown. Product indicators are empirically correlated with physical and chemical quantities, but process properties can also be employed as product indicators. All product properties characterize information that can be acquired by using sensors.

"Technological" and "Physical" Test Procedures. Some fundamental problems in establishing material properties are illustrated for the case of rubbers [406].

Technological Test Methods. The testing and characerization of chemical substances is generally limited to assessment based on technological tests or application-oriented model tests, which are single-point measurements which have limited predictive power and do not take account of the functional relationships actually present. Technological tests do not directly lead to conclusions about the physical and chemical properties of chemical substances. This means that such data alone are insufficient as a basis for the optimization of chemical production processes.

The essence of technological testing can be illustrated by a simple diagram (Fig. 129). A certain material M_j under a certain load X_i exhibits a technological behavior Z_{ij}.

Figure 129. Technological inspection [406]

When the test load (generally complex) is specified in terms of the arbitrary design of a testing machine, the actual loading often cannot be expressed physically. For example, the Mooney tester [407–409] has an inconsistent shear rate and inhomogeneous stress and temperature distributions in the steady state. Furthermore, the variation of temperature with time during the measurement varies in an uncontrolled way as a function of the specimen used. The single-point measurement performed, namely the torque after 4 min, describes only an integral response of the material relative to the test-chamber geometry as the specimen is subjected to a load that is neither homogeneous nor steady.

The predictive power of this measurement is thus limited to comparison of materials under these conditions. In general, no certain conclusion can be drawn as to the processing qualities of the rubber tested in this way, since the shear loads that occur in industrial processing machinery are several orders of magnitude higher.

Physical Test Methods. A material can be better characterized in terms of its physical properties. These quantities are obtained by applying simple loads and measuring the relationships between load and response. Such simple loads include linear, uniaxial stress, laminar flow at constant shear rate, and a steady homogeneous temperature distribution in the specimen. Complicated loading modes such as occur in practice can generally be synthesized by superimposing simple loading states.

The material properties M_{ij} are material-dependent quantities described a functional relation:

$$Z_{\mathrm{ij}} = f\left(M_{\mathrm{ij}}, X_{\mathrm{ij}}\right) \tag{5.1.1}$$

For example, Hooke's law

$$\tau = G\gamma \tag{5.1.2}$$

describes the behavior of many elastic solids. Here, the stress τ is the load ($X_j = \tau$), while the deformation or strain γ represents the material behavior or response ($Z_{ij} = \gamma$). A material constant, the shear modulus $G = \tau/\gamma$, interrelates these two quantities and characterizes the mechanical properties of the material ($M_{ij} = G$).

Figure 129 shows that the technological behavior is governed by the material and the loading. The task of a phenomenological theory is to define the formalism that describes the observed relations (Eq. 5.1.1) and the properties M_{ij} of the material (Fig. 130).

Figure 130. Physical inspection [406]

Idealized models of substances and bodies play a major role here, for example the ideally elastic (Hookean) solid, the Newtonian fluid, and the Maxwell and Voigt bodies (Fig. 131). Deviations from the behavior of the idealized body are handled by restricting the range of validity (Hooke range) or by introducing correcting relations. For example, the viscosity of a general non-Newtonian fluid is described by

$$\tau = \eta \mathrm{d}\gamma/\mathrm{d}t \tag{5.1.3}$$

where τ is the shear stress, $\mathrm{d}\gamma/\mathrm{d}t$ is the shear rate, and the viscosity is treated as a function of the shear rate $\mathrm{d}\gamma/\mathrm{d}t$,

$$\eta = \eta\left(\mathrm{d}\gamma/\mathrm{d}t\right) \tag{5.1.4}$$

Figure 131. Rheological model [406]

The phenomenological theory describes the physical properties of a material by interrelating the load state and the behavior of the material, whereas polymer physics seeks to devise a theory that correlates the physical properties of a material M_{ij} with the chemical composition and structure of the material or a structure model (e.g., Kuhn coil model [410], Pechold link theory [411]); see Figure 132. If this were achieved, there would be a basis for the planned development of particular polymers.

Among the most important properties of elastomers is the viscoelastic behavior. There is still no self-contained phenomenological theory to describe the entire mechanical deformation behavior, including fracture. For small deformations, relaxation spectroscopy [411] can

be used for complete determination of the viscoelastic behavior of polymeric materials. Under harmonic loads, the complex shear modulus $G*(\omega,T)$ is measured as a function of frequency ω and temperature T. The results can be used to calculate the relaxation time spectrum $H(\tau_R,T)$ (τ_R = relaxation time), which is closely related to the structure. Using the Boltzmann superposition principle allows the material behavior under complicated, nonharmonic loads to be calculated.

Figure 132. Physical inspection and structural theory [406]

These methods fail at large deformations, where the relation between stress and strain becomes nonlinear. The Boltzmann principle, which states that the effect of a composite load can be treated as the sum of the effects of its composite simple loads, does not apply in such cases. Fundamental findings and results on the material properties of multiphase chemical substances, including these application-relevant ranges, can be found in [412–414].

The question arises to what extent the mechanical behavior of elastomers can be completely characterized despite the lack of a unified nonlinear theory of viscoelasticity. NINOMIYA and FURUTA [415] proposed that in general four functions are sufficient to characterize the deformation behavior:

- The relaxation time spectrum $H(\tau_R)$, which characterizes linear viscoelastic behavior at small strains
- The stress – strain curve $\tau(\gamma)$, which characterizes the nonlinearity
- The fracture strain $\varepsilon_B(T)$, which characterizes fracture behavior
- The shift factor $a_T(T)$, which characterizes the temperature dependence [416]

Such a description of a polymer, however, requires substantial efforts. To determine the relaxation time spectrum and shift factor, the complex modulus must be measured over a wide range of temperatures and frequencies. Moreover, extensive calculations must be carried out.

The difference between technological and physical test methods can be summed up as follows: Technological tests investigate the behavior of the material in an application-oriented model test, generally involving a single-point measurement under complex loading conditions. In contrast, physical tests are concerned with the fundamental behavior of the material. Simple and easily quantifiable loading modes are selected and then varied such that the fields of properties are determined in multidimensional product spaces (see Fig. 404).

Despite the obvious advantages of the physical analysis, technological tests will continue to be important because of their lower cost.

A crucial point in selecting a method is the purpose of testing. Three aims must be considered:

1) Product characterization in general, in the sense of quality assurance (e.g., DIN ISO 9001 [417])
2) Acceptance testing and production control
3) Prediction of the practical behavior of a material

The objective of product characterization is to achieve at the most complete possible description of product properties in terms of instrument-neutral physical quantities, to determine the key parameters that affect the product properties, and to quantify functional relationships.

Accordingly, product characterization encompasses the area of physical testing. The demands on instrumentation and the amount of work required for interpretation are so great that these methods are generally only justified for new or as yet unknown products. This is the only way to carry out a reliable, exact comparison between materials.

As a technique for routine inspection, for example in acceptance testing and production control, sampling inspection of material properties is generally adequate. Sampling techniques (re-

presentativeness over space and time) are applied to both the quantity of material and the selection of loading mode combinations. The principles of statistical quality control should be observed [418].

The creation of correct, optimal experimental designs, however, presupposes a comprehensive knowledge of material properties.

The requirement on acceptance testing procedures is that they can be performed by the vendor at one location and the buyer at another, using different instruments. The parties must agree on the test conditions (establishing the controlling parameters); this is one of the key tasks of international standardization (e.g., ISO). In contrast to product characterization, single-point measurements may be relevant here as well.

In production control, various batches of a product are subjected to spot checks to verify that they have identical physical properties. The important prerequisite is good reproducibility of measurements on a given instrument. It may be desirable to choose complex test conditions in the interest of quick, effective monitoring [419].

There are two possible approaches to forecasting the mechanical and technological behavior of a material in practice. First, tests can be performed under the process conditions and loading modes encountered in practice; this step should be preceded by a thorough analysis of the process (see Section 11.3 with Figs. 395 and 396). Second, in principle it should be possible, given suitable results from the determination of the physical material properties, to calculate in advance how the material will behave under the required loading conditions. The second method, however, often runs into the difficulty already mentioned: the lack of applicable theories. For this reason, the first approach (simulation of practical conditions) is becoming the more important.

By analogy with this example of mechanical product properties, the electromagnetic product properties defined by Maxwell's equations

$$\boldsymbol{D} = e\boldsymbol{E} \tag{5.1.5}$$

$$\boldsymbol{L} = \mu\boldsymbol{H} \tag{5.1.6}$$

$$\boldsymbol{I} = \sigma\boldsymbol{E} \tag{5.1.7}$$

can be examined. The first product properties determined here (generic class "application features") are due to molecular motions and are measured as collective phenomena. For example, suitable spectroscopic or chromatographic methods make it possible to resolve the required product reactions over a variable frequency and temperature field:

$$e = e\,(T, \omega, ...) \tag{5.1.8}$$

Again, the limit of the linear relations is found by considering the variation of the field quantity:

$$e = e\,(T, \omega, E) \tag{5.1.9}$$

The product properties are in general complex:

$$e^* = e_\mathrm{r} + ie_i \tag{5.1.10}$$

Model-Aided Measurement Procedures for Determining Product and Process Properties. From the connection between process model and information demand, it is possible to identify ways and means of overcoming the limitations of sensor technology by utilizing the present capabilities of information processing (see also [380]). The broad potential of model-aided methods, which has been under-exploited in process engineering, should be mentioned first (see Fig. 133).

In the context of intelligent sensor systems, this procedure makes it possible to reconstruct unmeasurable process and product properties from measurable quantities by interpreting a priori knowledge about the process in the form of a mathematical model. Ideally, the entire process state can be derived from the available measurements in this way. By integrating a priori knowledge into the measurement process, the predictive power of measured quantities is markedly enhanced in both scope and reliability.

The prerequisite, however, is a sufficiently accurate mathematical model of the process under consideration [420–424]. Especially in chemical process engineering, however, mathematical modeling presents some difficulties. Many processes, because of their complex nature, do not lend themselves to accurate mathematical description. Process facilities often include subprocesses that are not subject to the classical mathematical model-building procedure.

Figure 133. Model-aided measurement procedure

In such cases, for example where the product properties and their relationships can be described only in qualitative terms, new ways of incorporating a priori knowledge about the process into the measurement must be sought. The methods of applied information processing can be expected to reveal new solution approaches. Under some circumstances, verbally formulated algorithms and heuristic methods can lead on to a qualitative description of the process. The use of knowledge-based methods is more and more attractive, for example the inference methods employed in expert systems [425–427] and fuzzy-logic methods [428–430].

Interesting tasks arise here for future research. An initial approach was the project "Technical Expert Systems for Data Interpretation, Diagnostics, and Process Control (Tex-I)," in which several participants (Siemens, Interatom, Bayer, and others) attempted to adapt expert systems techniques to process control. Other projects in this context are SENROB and NERES [431].

It is to be hoped, however, that the practical benefits of model theories will be studied and utilized more intensively than in the past. However, casual use of modern or simply fashionable modeling methods to make up for shortage of process knowledge must be avoided [380].

Figure 134 outlines a model-aided measurement technique for the case where a mathematical process model is available. The mathematical model is set up in parallel with the process and run (simulated) in real time (for example on a mi-

Figure 134. Schematic diagram of model-aided measurement procedure

Figure 135. Structure of a model-aided measurement procedure

crocomputer). The known controlled variables acting on the process are supplied to the model as inputs. The class of model-aided techniques includes the Kalman filter and the Luenberger observer. These are similar in their fundamental structure, differing in that the Kalman filter is designed on a stochastic basis while Luenberger observers are designed by deterministic methods. The structure cited here applies to both continuous and batch processes.

In general, the properties of starting materials are interpreted as inputs, since they fix the starting conditions. They are therefore fed to the model as inputs, together with the controlled variables acting on the process actuators.

It is tempting to use the model to reconstruct the unmeasurable part of the process state in view of all knowledge about the inputs. A variety of problems arise, however. Even if an exact model exists, the simulated process state may coincide with reality only when the initial conditions selected for the model are identical with those of the process. But the initial conditions of the unmeasurable state components are generally also unknown. Further, it must be assumed that unavoidable modeling errors and perturbations acting on the process will lead to increasing divergence between the actual and simulated state variables. Forcing convergence between the model and the process, regardless of the selected initial conditions, perturbations, and error effects, means taking corrective action in the model. This can be done by comparing the actual measured process and end-product properties with the same properties calculated from the simulated process state with sensor models. If the resultant difference signals are then amplified in a suitably designed correction element, the correction can be made in the process model itself. The chief problem is to design the correction element in such a way that the behavior of the model will converge to that of the real process as rapidly as possible.

Figure 135 shows the structure of a model-aided measurement method in a simpler form. Here, the product properties and the controlled variables of the process have been combined into a single multidimensional input vector. Similarly, the output vector includes all the measured properties of the process and of the end products. The block diagram clearly shows that the process model, via the measured output variables, is made to track the real process in the manner of a servo follower. The correction element, acting as a controller (closed-loop controller), compensates for differences in behavior between the real process and the model resulting from perturbations, modeling errors, and incorrect initial conditions. In the case of the Kalman filter, it is generally assumed that both process noise and measurement noise act on the plant [420, 432]. Under the assumption of certain properties for this stochastic perturbing signal, the correction element is designed such as to minimize the expected value of a quadratic function of the difference between the actual and estimated process states. In the design of a Kalman filter, the a priori knowledge thus includes not only the pro-

cess and sensor models but also models of the two stochastic processes. In the case of a Luenberger observer, in contrast, the design process is purely deterministic [421,423].

For this concept of estimating or reconstructing the process state to work in a satisfactory manner, it must be insured that the process can be observed by means of the measurable quantities. In other words, all components of the process state manifest themselves in various ways in the time variation of the measured process and product properties. Criteria are available for investigating the observability of a process [420, 421]. Examples of applications in process engineering can be found in, for example, [433].

The discussion to this point has related to the determination of process and product properties in general; measurement and test methods employed in the laboratory, pilot plant, and industrial plant must meet some additional requirements. This chapter is exclusively concerned with measurement in the plant itself, or in an environment close to the process or similar to it. In the past, this subject was referred to as process metrology, or, when analytical questions were being emphasized, process analysis.

The dividing line between these two fields is fluid, and often they are inseparable. It is therefore proposed that only the distinction between process-level (local) and remote sensor system technology be preserved, so that process sensor system technology becomes an appendage of the well-known field of laboratory metrology [434] in which special requirements have to be met.

The computer processing of information from the sensor system changes the profile of requirements. In manual operation, measured values are commonly interpreted and processed by an expert plant operator. In this form of information processing the fault tolerance and error rate depend on the plant operator's level of experience and knowledge.

Computer processing imposes the following new requirements on the sensor system:

- Reliability at an acceptable maintenance cost
- Functionality even in extraordinary process states (startup, shutdown, disturbances)
- Accuracy [435] and dependability

These requirements result from advances in microelectronics that make computerized information processing a possibility. Microelectronics is also an important tool for the realization of these requirements. After optimization of the instrumentation and installation, the design of intelligent sensors with the ability to report faults and initiate maintenance procedures automatically is in many cases the most economical way to satisfy the requirement of reliability.

The requirement of functionality even in extraordinary process states implies not only robustness but also a thorough understanding of what happens on in the process. Especially in sensor systems used to measure quantities that depend on the composition of the measured stream, many independent variables must be handled, and up to now it was only rarely the case that these were known for all possible process states.

Measurement (from the physicist's standpoint) becomes metrology (from the eingineer's). It is not enough that a method works in principle; it is essential that it always functions effectively [436].

The use of computers for information processing, however, makes it possible to acquire information more economically than before. In signal-oriented process control, the motto was: "Acquire information item by item, in parallel, and always," whereas information-oriented process control engineering follows the principle: "Acquire information in the smallest possible amount, but as much as necessary, and only then when it is to be used" [437].

The advantage, especially in batch processes, is obvious. Large savings are possible in the wear-out reserve (see Section 11.4 and Figs. 420, 421) and thus in maintenance costs if, for example, a pH probe in a reaction vessel is brought into contact with the product only when the pH must be measured and otherwise is held in a protected standby condition (see Section 5.3 and [438]).

The new requirement profile and the new principle of information acquisition have influenced not only instrumentation but also the interface between the sensor and information-processing systems (Fig. 125). Information coupling, for example to a process control system, is no longer limited to the transmission of a measured value. Sensor status messages can also be included (e.g., reports that a unit has failed or malfunctioned or that a maintenance procedure is under way), and it should also be possible for

Figure 136. Information flow in sensor systems: Temperature measurement with a jacketed thermocouple

the sensor system to receive information from the process control system (e.g., an instruction to hold itself available; see Figs. 136, 137, 138, 139, 140, 141, 144, 145, 146, 147). The same holds for actuator systems (see Section 6.1).

The definition of the extended interface between the sensor and information-processing systems should also include the signal levels and types and the signal contents.

Besides the change in emphasis as a result of computerized information processing, new measurement functions are being assigned to sensor technology (as they have been throughout the development of this technology). When existing processes, such as polymerizations, are automated and optimized, the need for information is reconsidered and new constraints applied, with

Figure 138. Information flow in sensor systems: temperature measurement with jacketed thermocouple and signal processing

Figure 137. Information flow in a simple sensor system [389]

Figure 139. Information flow in sensor systems: sensor system with compensation (e.g., pH measurement with temperature compensation)

Figure 141. Functional groups of a process analyzer (gas analyzer) [389]

Figure 142. Continuing development of sensor system technology

the consequence that new measurement tasks are created or an old task is accomplished. The introduction of novel processes (e.g., biotechnology) involves new problems for sensor technology [439,440] (see Section 5.3).

The requirements that must be met in the further development of sensor technology for production processes fall into two independent classes (Fig. 142):

Figure 140. Information flow in a sensor system with auxiliary energy and signal processing [389]

Figure 143. Development of the magnetic induction flowmeter (MID) illustrated by power consumption over time [441]
a) Introduction of switched d.c. field; b) Introduction of compact devices; c) Introduction of microprocessor control

The changed profile of requirements and the need for higher availability in computerized information processing mean that existing sensor systems must be enhanced. An example is the development of the magnetic induction flowmeter. In 20 years, the power consumption – a key factor in internal heat generation, service life, overall dimensions, etc. – has been reduced by a factor of 20 (Fig. 143) [441].

New problems require the development of new methods. Again, the realization of technical systems, often based on well-known methods of physics, is facilitated by the new capabilities of microelectronics and modern materials. Examples are systems using the Coriolis force to determine mass flow rate and others using the radar principle for level measurement.

5.2. Process Sensor System Technology

Information Flow in Sensor Systems. Section 3.5 showed that it is desirable to separate the precise description of the technical properties of an individual instrument from information about its technical function (Fig. 65). This makes it possible to maintain required functionality even when instruments are replaced.

Thus it is advantageous to apply the same formalism to information transformation (from the measured property of the material stream to the output signal) that was employed in structuring the material flow in production processes [386]. This leads to the idea of information flow in the sensor system, whereby a sharp distinction is made between the form taken by the desired information after each transformation step (corresponding to the product elements in the production process) and the metrological process steps required for information transformation (corresponding to the process elements of production).

As an example of a simple sensor system, Figure 136 illustrates the measurement of temperature with a jacketed thermocouple.

The measured property E of the stream is coupled to an intermediate medium and thus transferred to the latter.

The intermediate medium with property Z now interacts with the sensor element, which transforms Z into an electrical output signal S.

The information flow between the process and a simple sensor system is illustrated, in abstract form, by Figure 137 [389, 442].

It is usually necessary to amplify and condition the electrical output signal of the sensor element (Fig. 138):

The electrical output signal of the sensor element S'' is amplified to give a signal S'.

This amplified signal S' is linearized, mapped onto a unit interval, and made available as a signal S at the sensor system output.

The term *integrated sensor* refers to a system in which the functions of coupling, interaction with sensor element, and signal conditioning are integrated in a single component. If signal processing is included, the term *intelligent sensor* is used, especially when signal processing involves complex calculations and range matching steps [443].

In a simple sensor system with compensation (Fig. 139), an additional sensor is needed to de-

Figure 144. Information flow in a sensor system with sampling and other auxiliary functions (disposal, delivery, etc.) [444]

termine the parameter whose conditioned signal is incorporated into the signal processing. Auxiliary energy is generally required for this purpose; in abstract form, Figure 137 is elaborated to Figure 140. The energy needed for signal conditioning and signal processing is supplied to the sensor system by a power supply device that must be analyzed independently as far back as the design stage.

Sensor systems in production processes are often highly complex in structure. Figure 141 shows the conventional representation, for the example of a gas analyzer [389].

Here, the measurement proper is preceded by the functions "sampling," "sample transport," and "sample preparation." Sampling has the task of acquiring a representative sample of the stream to be measured. The sample must be transported without alteration or falsification to the analyzer, which performs the actual measurement. This stage of sample transport often involves conveying the sample over a long distance. The "sample preparation" function involves adapting the properties of the process stream at the sampling point to conditions compatible with the measuring instrument itself. The measured property of the stream – for example, the concentrations of certain components in the stream – must naturally be preserved in a well-defined way. The planning and execution of sampling, sample transport, and sample preparation are strongly dependent on the properties of the stream material, the analytical objective, and the measuring method employed. This strong application dependence is the reason that sensor systems for determining composition-dependent quantities are complex in structure and must be serviced by specialists.

Along with the sensor system modules just described, Figure 144 also shows the functions "delivery" and "disposal." The disposal step matches the properties of the sample stream at the analyzer output to the permissible conditions at the point of return to the stream. The delivery function modifies the auxiliary energies and substances such that they can be utilized in the sensor system. Both these functions must be included in the diagram of the entire system because the correctness of the measurement also depends on them and because they are potential sources of error for the sensor system as a whole.

On grounds of economy, it may be desirable to withdraw samples at various points in the process and measure them with a single analyzer. The functions of sampling, preparation, and transport are then preceded by a measuring point selection step (Fig. 145). In combination with signal processing for each sampling point, this function correlates the analyzer output signals (S_1 to S_n) with the properties to be determined (E_1 to E_n). Conversely, several analyzers can determine a variety of values on a single sample by accessing the same sample preparation.

As in the case of the production process, monitoring and control systems must also be available for complex sensor systems. All complex sensor systems include for this purpose auxiliary devices such as displays, pressure gauges, flowmeters, or valves for the admission of cal-

Figure 145. Information flow in a sensor system with sampling, auxiliary functions, and integrated dedicated computer [444]

ibration substances. In more abstract terms: the background functions grouped together as "functional check, control of maintenance procedures, and setting of parameters" must be supported as a minimum [442].

These functions are performed manually in conventional sensor systems. At intervals specified by the maintenance strategy, the system is inspected and serviced (e.g., calibrated) by maintenance personnel. However, analogous to the production process, this routine activity is increasingly being automated (Fig. 145) and turned over to a dedicated computer system that monitors all the basic functions of the system, controls procedures, and executes corrective actions. For this, the dedicated computer requires system-internal sensors and actuators. The computer furnishes status information about the sensor system and can execute incoming instructions, for example, to come into action in an intermittent mode (on-request or on-event). The outcome is a general structure for complex sensor systems. The information blocks K and S are the basis of the protocols for the future field bus.

"Intelligence" and Sensor Systems. In an intelligent sensor system, the functions discussed above are integrated or are supported in such a way that it can be regarded as a sensor system with communication capabilities. In Figure 146, these links are provided by a field bus, whose function could equally well be carried out by the use of smart technology based on the HART protocol.

In what follows, the functions of sensor systems are described as classical or intelligent.

Classical functions include:

- Sensing functions, i.e., transformation of physical and chemical effects into a signal suitable for downstream processing
- Signal conditioning (e.g., amplification)
- Signal output (part of the signal processing, such as A/D conversion, takes place in the local or process-level components)

Intelligent functions include:

- Signal processing
- Interconnecting measurements to expand information
- Auxiliary functions for on-line metrology
- Automatic execution of maintenance functions
- Failure strategies (see Fig. 138)

Figure 146 illustrates classical and intelligent sensor systems and their incorporation in higher-order information-processing systems. The use of a field multiplexer for the connection to the process monitoring and control system bus,

Figure 146. Movement of information processing nearer the process level

which is already a practicable transition approach (even in explosive environments); see Section 5.5.

The intelligent functions of a sensor system can be employed in a five-point program:

- Making all the needed information available
- In a form suited to the application
- At the proper time
- Ready for downstream processing
- Even in extraordinary process states

The goal of this development is to devise autonomous field-level devices that will automatically perform functions such as the maintenance functions of DIN 31 051 [445] discussed above. Intelligent process pH sensor systems can already carry out functions such as electrode cleaning, zeroing, calibration, flushing, and so forth, either "on-event" or "on-request."

Communication with Process Sensor Systems. Consideration of the functional scope of complex sensor systems leads to the question of how the sensor system can appropriately communicate with information-processing systems. The output signal categories M (messages), B (instructions), and S (signals) are the information blocks involved in communications (K) with process control and automation systems. A straight point-to-point connection with communication in one direction does not meet modern requirements. The need for bidirectional, open communications structures, and messaging services is essentially derived from the functions discussed above. More detailed information can be obtained from the literature on field buses [446, 447].

The connection of a classical sensor system to a local component (LC) is a unidirectional link employing a uniform signal such as 0 – 20 or 4 – 20 mA (Fig. 126-9). All that is transmitted is the measurement signal or a report of a device failure. Signal processing, that is, conversion to a value with a physical unit, takes place in the LC. Maintenance tasks must be performed locally in the sensor system. According to DIN 31 051 [445], these include inspection to evaluate the actual status, maintenance to preserve the nominal status, and repairs to restore

Figure 147. Functional breakdown of the sensor interface K (communications; see Fig. 145) into "process port" and "engineering port" [389]

the sensor system to nominal status. General discussion of these points can be found in Section 11.4.

If a dedicated computer performs the function monitoring of the intelligent measuring system and carries out simple maintenance procedures, using messages to report on both activities, the process sensor system acquires, functionally, a second interface (in addition to information delivery to the control room via the "process port"), which mediates information exchange with the engineering team via the "engineering port." This functional distinction is illustrated in Figure 147.

Given the wide range of methods employed in process sensor system technology and the broad spectrum of application-specific hardware configurations, the only way to achieve system-wide reliability and effective maintenance is by unifying the two interfaces, process port and engineering port. A flexible dedicated computer system, matched to the structure of complex process sensor systems, can organize the required information exchange from and to the sensor system. In this way, expensive custom solutions can be avoided and replaced by acceptable, standard solutions.

Information Exchange with Local Functional Units. According to SCHMITT the following holds for information exchange between the field level and the process monitoring and control system: "As little as possible – as much as necessary" [437]. This requirement governs the functional sensor interfaces shown in Figure 147 and is discussed further in Figure 148 in application to the process port.

Figure 148. Information exchange between sensor system and local process control system component (LC) [389]

In relation to local (process-level) functions, the sensor system has only one task: making the measured value available in proper form. If the sensor system ceases to respond as specified because of an upset of malfunction, this fact should be reported in a group message "Failure" (M_1), which is to be forwarded directly to the display and control component of the control system (see Chapter 7). Any still-pending measurements are then rejected as unusable. This assessment of sensor information presupposes that the sensor system monitors its own internal technical functions.

If internal sensor function monitoring is initiated automatically or manually, measurement signals may appear momentarily that are correct in content but have nothing to do with the process and product properties being measured. This state is indicated by the status message "function monitoring" (M_2). Because of the absolute priority of the information measurement signal, it may be necessary to permit such nonavailability due to internal programs in the sensor system only when they can be tolerated by

the control system. An instruction "release" (B_1) from the process control system to the sensor system is a suitable way of handling this situation; for example, the instruction can inhibit or enable the calibration procedure.

The power and low cost of modern microprocessor boards make it possible to use them locally to optimize internal operations in sensor systems without having to shift such functions to central systems. In this way, straightforward system structures can be created. For the sake of manageability, information exchange with process-level functional units of the process monitoring system should be restricted to the measurement signal plus a few status messages and instructions. The handling instructions and procedures associated with each type of status message or instruction should be defined as a strategy in the process control system (for status messages) or in the sensor system (for instructions).

Information Exchange with Engineering Functional Units. The maintenance functions have the task of keeping up reliability and insuring availability. Routine inspection and function monitoring jobs should be automated and turned over to the sensor system itself whenever technically possible at reasonable cost. When service is needed or when a malfunction occurs, the engineering group is requested. From a functional standpoint, access to the sensor system and necessary information exchange take place over a separate interface, labeled "engineering port" in Figure 147.

If a process sensor system is fully equipped with self-monitoring functions and devices to maintain the functionality of both the instrument proper and the sample preparation part, the volume of information produced is difficult to manage without structuring. Engineering becomes inefficient and personnel find themselves overloaded if the separate functional concept and distinct operator interface of each instru-ment type and each manufacturer have to be kept in view.

The capabilities of future field-level communications are discussed here, based on analyses of information structuring for process analyzers [389].

For efficiency in engineering, it is proposed that information exchange (see Fig. 149) be accomplished in three functionally distinct information "planes" differing in complexity. A status summary is needed for the instrument proper; this includes a group message "failure" when the measuring device is no longer reliably available; a status message "function monitoring" when the sensor system is occupied with itself as a result of a manual intervention or automatic program; and the display "measurement" so that the engineer can make an on-site assessment. If the sensor system is equipped with self-monitoring functions that can detect a failure (for example due to drift in the analyzer or exhaustion of the test gas supply), the status message "maintenance required" should also be displayed.

Figure 149. Structuring of the interface to engineering [389] DCC = display and control component; EN = Engineering

The inspection, maintenance, and repair of process sensor systems need not always involve specialists. It appears useful to be able to distinguish whether a given malfunction can be

remedied by simply replenishing auxiliary substances or replacing an electronic component, or whether the device can be put in service again only after a specialist works on the sample handling system or the physical part of the instrument.

For this purpose, the first engineering (EN) plane includes simple, binary diagnostic indicators. The "failure" message may, for example, be broken down into just three categories: M_{11} if there are problems with the delivery of auxiliary supplies or energy; M_{12} if there are problems in the measuring section, including sample preparation; and M_{13} if a failure occurs in the electronics. For general maintenance, simple instructions such as manual initiation of a function check should be integrated into this EN plane.

This initial diagnostic feature requires communications with the sensor system above and beyond a simple status indication. These communications are carried on through a display and control component near the sensor level. The display and control component can take the form of a keypad with display integrated into the sensor system; an engineering computer some way off; or a portable unit such as the handheld monitor shown in Figure 146, which is plugged into the sensor. As to what technical and functional capabilities exist and how they can be exploited, see [446,448].

Detailed diagnosis of the causes of malfunctions, which can only be performed by process sensor specialists, should be carried out in a second engineering plane, via one of the functional units. This kind of diagnostics includes single-fault analysis upon a system failure, as well as detailed need analysis upon a maintenance request. The design and commissioning of complex process sensor systems often include configuration and parametrization. These tasks are also performed by specialist personnel and thus form part of the second EN plane. For the manageability of process sensor systems, it is important that the system data be kept updated and that retrospective documentation be maintained.

When such a ternary structure is used in the EN interface, standardization across vendors and instruments appears possible at least for the status summary and the first EN plane [449]. For efficient maintenance, it would also be desirable if information exchange through the second plane could be structured in a consistent way and mediated by operator interfaces as similar as possible.

The "sensor-level display and control component" function is increasingly being implemented with a portable computer (laptop PC). If a standardized operating system and graphics environment are employed, vendor- and device-specific parametrization and diagnostic routines can be loaded and run in software. For process analyzer technology at least, such a consistent engineering tool offers substantially greater benefits than a variety of individual solutions with their associated library of manuals (see also [450]).

The communication ports of field-level devices should generally be implemented on the basis of the object-oriented model [451] defined by the MMS (Manufacturing Message Specification; see Chapter 8 and [452,453]). The field device plays the role of server and performs the services requested by the client; see Figure 150.

Figure 150. MMS communications objects

Linked with the cited background functions and their use for process control, maintenance,

Figure 151. Determination of instrumentation costs

and design (configuration) tasks is the introduction of general, standardized descriptive languages for field-level devices; these are called Device Description Languages (DDLs). The objective of manufacturer-neutral field-level functions is that the field device to be operated should be addressable without any special knowledge of the physical device, even if devices are modified or replaced by hitherto unknown devices. Standardization efforts toward a universal device description are focused on creating a proposal for the ISA SP 50 international field bus standard [446, 454].

Furthermore, it is not sufficient to solve the problems of field-level communications without taking up questions of what user interfaces are appropriate for sensor systems and how these interfaces can be standardized [450, 388]. The application connected above the communications services must be dealt with at the same time. On practical grounds, a variety of devices having the same function must not have unlike operator interfaces [446, 455].

Moreover, the rapid growth in information demand and the need for auxiliary energy in process sensor systems – which may well exceed the permissible limits in intrinsically safe systems – have made it essential to consider separating the information and energy channels (see Section 5.5, Chapter 8, and [447]).

Determination of Instrumentation Cost. Given the information economy of a process modeled with the phase model (see Figs. 125 and 36), the instrumentation outlay can be determined at any level of detail (see Chapter 2).

Consider, for example, the process step of neutralization in a wastewater treatment process. Among the quantities to be determined are the pH and the inlet flow rate of the wastewater (Fig. 151). From the categories and attributes of the process property (here the wastewater pH), the property can be methodically assigned to a suitable sensor system. A CAE tool for this purpose, accessing a source database for sensor – actuator systems, is discussed below.

Figure 152 shows an example of how to structure a taxonomy of sensors for process engineering. The user is guided by generic attributes: application features and design features. For the wastewater pH example mentioned above, a sensor system can thus be defined that has the application features on-line measurement, determination of a collective property, measurement in the product stream, and so forth. In general, the requisite instrumentation cost can thus be determined from the information demand obtained from the phase model. Sensor or actuator systems are selected on the basis of the category of process and product properties, with the aid of a taxonomy of such systems (navigation, hypermedia, etc.). Manufacturers still offer

Figure 152. Taxonomy of process sensor systems: System properties required for determination of pH and BOD_5

monogram-like selection aids [456], which will certainly be replaced soon by expert-systems tools.

Taxonomy of Sensor Systems. The classical listing in book form, arranged by apparatus features, is no longer adequate for presenting an up-to-date survey of application options for modern sensor systems.

Nevertheless, such proven classics as Profos [457], Strohrmann [458], Hengstenberg [459], or the Kohlrausch [460] are indispensable aids. The journals TM, atp, and MPA have presented thorough surveys of problems and solutions (see also [388, 461–463]). However, in general, encyclopedic treatment must be replaced by structuring.

A priority task for structuring available sensor systems in a way relevant to process control engineering is to emphasize those features that actually bear on potential applications. As discussed previously, these features cannot be identified without a knowledge of process conditions met with in practice; that is, an apparatus-oriented analysis alone is insufficient. Instead, the conceptualizations introduced to structure information characterizing a production process lead to a powerful technique. In future, this approach may serve as a basis for developing powerful CAE tools for the systematic instrumentation of new plants.

Figure 9 shows that, if the distinction between function and substance – or function, function-generating procedures, and devices (Fig. 65) – is taken into account, then the world of sensor systems can first be represented in terms of the tasks meaningful in certain industries; see Table 3 [464] and the lower row of Figure 153.

Table 3. Letter symbols for process control point functions [464]

Letter symbol	Group 1: measured values and other input quantities		Group 2: processing (as trailing letter)
	As first letter	As additional letter	
A	alarm		
C			controlling
D	density	difference	
E	all electric variables		sensing element
F	flow rate	ratio	
I			indicating
L	level		low
P	pressure or vacuum		test point connection
Q	quality, e.g., analysis, concentration, conductivity	integrate or totalize	integrating or summating
R	nuclear radiation		recording
T	temperature		transmitting

Figure 153. Taxonomy of process sensor systems: Breakdown of sensor functions

The E – R (entity-relationship) modeling technique described in Chapter 2 is employed, at various levels of hierarchical detail, for this purpose. Such an ordering rule, as explained in Chapter 2, is known as a "taxonomy" (Greek: taxis = order).

Generic Class: Application Features. The generic class of application features or task features, defined from the functional viewpoint, becomes the uppermost level in this context.

The following are employed as classification criteria:

- The attributes of the object classes of technical processes
- The degree of indirectness with which the measurement signal is determined
- The ratio of relaxation times between the acquisition of the measurement signal and the variations of the property of the stream being measured (see Section 5.1)
- Specification of the components of the substance measured

Under these criteria, sensor systems are now classified according to whether they determine product properties or process properties, whether they operate on-line or off-line, whether they are employed in-line or ex-line, whether they can determine collective or specific properties, and whether they are usable in homogeneous or heterogeneous phases.

These generic features are explained briefly below:

- On-line: A continuous correlation is possible between information provided and properties of the process or product. The essential condition for on-line measurement is that the relaxation time of changes in the process or product properties must be markedly longer than the time required to acquire, convert, and deliver the information $[\tau_{\mathrm{R(property)}} \gg \tau_{\mathrm{R(sensor)}}]$ (see also Section 5.1).
- Off-line: Discontinuous measurement; determination of sampling intervals requires knowledge of process characteristics (e.g., kinetics).

This pair of attributes describes the problems the (process) sensor system must handle in terms of communications.

- In-line: The systems used to prepare information about the process or product properties interact directly with the product stream (or a bypass stream).
- Ex-line: The required sampling operation (extractive) makes it necessary to take into account additional changes in the properties of the stream substance.

Questions of positional and temporal representativeness are extremely important here. This

Figure 154. Taxonomy of process sensor systems: breakdown of sensor principles for the example of temperature measurement

pair describes the problems the system must deal with in terms of metrology.

- Collective: The quantity measured can provide information about the quality of the stream as a whole (e.g., density or flow rate), its reactions (e.g., pH, conductivity), and the relationships between its properties (e.g., relative concentration).
- Specific: The "manifestation of a property" determined makes it possible to gain qualitative and quantitative information about individual components of the stream; such techniques include analytical methods such as spectroscopy and chromatography.

This pair thus states clearly whether the chosen sensor system yields information about atomic/molecular, mechanical, and electromagnetic mechanisms.

- Homogeneous: The sensor system can acquire information only in homogeneous phases (e.g., flow-rate measurement with a mass-flow anemometer).
- Heterogeneous: The sensor system permits the determination of the measured quantity even in heterogeneous states of aggregation, such as dispersions (e.g., flow-rate measurement by the Coriolis principle).

This pair accordingly requires an unambiguous description of the sensor system functionality with regard to its possible use in multi-phase environments.

Generic Class: Design Features. The next level consists of a further class of features which basically summarize information about the design of the sensor systems under consideration.

Sensor systems are classified by communications capability, design type, utilities required, material of construction, range of measurement, and manufacturer. Individual features can be further structured. The dependent lines in Figures 153 and 154 illustrate this point. In principle, the depth of structuring is unlimited.

To illustrate characteristic features of importance in field-level devices, the safety requirements on process sensor systems are discussed at this point. If "safety" is defined as a risk less than the limiting risk [403], as in Section 5.1, safety-relevant properties of a process sensor system

Figure 155. Safety requirements on process sensor systems

can be divided into two classes with regard to possible sources of danger:

- Properties related to insuring the availability and reliability of the sensor system itself
- Properties relating to reducing or preventing danger interactions of the sensor system with the system environment

These contributions to safety are correlated with possible technical safeguards in Figure 155. The potential dangers due to interactions with the environment are divided into those that require protection of the sensor system against the environment, and those requiring (possibly indirect) protection of the environment against the effects of the system.

As Figure 155 shows, present-day principles, guidelines, and standards on insuring the safety of process control hardware can be classified in the same way:

From a safety standpoint, enhanced availability and reliability gained through fault detection, fault reporting, fault compensation, and automatic calibration figure in the tendency toward increased functionality in field systems through integration of information-processing components, as discussed in this section. An initial and crucial requirement on the safety features of a process sensor system will be the ability of the system to verify and, if appropriate, report its complete functionality.

The protection of live or moving parts of an electrical device against foreign solid bodies or liquids is required by all national and international standards, for example, [465]. Because they are represented by the letter code IP (International Protection), these provisions are also referred to as IP protection types.

A topic still under vigorous discussion, in contrast, is how to insure electromagnetic (EM) compatibility. In German and European standards, electromagnetic compatibility is defined as the ability of an electrical device to function satisfactorily in its environment without unduly influencing this environment [466,467]. In Figure 155, measures to insure electromagnetic compatibility are divided into safeguards against EM interference induced in the device (static discharges, electromagnetic fields, and fast transients) [468] and safeguards against EM emissions into the environment, in particular human exposure, due to fields generated by the device or system [469].

Another type of protection incorporated into the field-level device is explosion protection [470]. The avoidance of flammable materials and explosive mixtures are usually the primary safeguards against explosions [458,471]. With regard to requirements on field-level systems, these practices are of relevance to design and material selection. Primary explosion safeguards must also be considered when analyzing the use

of sensor systems, especially the use of process control resources for plant security [401]. This area of applications includes all process control hardware employed for monitoring, protection, and damage limitation [472]; see also Section 10.4.

Secondary explosion protection in field-level process cotnrol systems includes all measures taken to prevent ignition of explosive substances by preventing energy transfer. The regulation governing electrical devices in explosion hazard areas distinguishes seven types of protection. Among these, intrinsic safety [473] sets rigorous criteria on integrated circuits in modern sensor systems (see Section 5.5).

For redundant and fail-safe design, see Section 10.4. Lightning protection practices are generally based on suppressor circuits [474].

The lowermost level is concerned with the physical, chemical, and other principles on which sensors operate. The commonly used nomenclature is set forth in DIN 19 227. Figures 153 and 154 show a selection of possible sensor principles; all others are indicated by the dependent lines. As in the case of the design features, further structuring is possible.

The foregoing application-oriented description can serve as a basis for a conceptual, object-oriented classification of sensor systems, differing sharply from the device-oriented and method-oriented structures, as listed below.

Methods of measuring "classical" quantities:
Temperature
– Resistance thermometer
– Thermocouple
– Radiative pyrometer
Pressure
– Elastic elements with capacitive, inductive, piezoresistive or piezoelectric signal conversion
Flow rate
– Magnetic-inductive
– Differential Level
– Hydrostatic
– Electrical and electronic
– Radiometric pressure

Nonspecific methods:
Density
– Radiometric
– Other
Viscometry
Thermal conductivity
Optical scattering and extinction
Acoustic

Group-specific methods:
Electrical conductivity
Flame ionization
Photoionization
Methods based on group-specific auxiliary reaction
Calorimetry

Specific methods:
Paramagnetism
Photometry
– Absorption (UV, VIS, NIR, IR)
– Diffuse reflectance
Gas chromatography
Liquid chromatography
Mass spectrometry
Electrochemical methods
– Potentiometry
– Amperometry
Titration
Analytical methods based on auxiliary reaction
– Chemoluminescence
– Absorption in aerosols or liquids
Special moisture measuring techniques

The concept presented here makes it possible to create flexible CAE tools, which will gain increasing importance in the design of process monitoring and control systems. For example, interactive and iterative equipment selection by the design engineer is aided by computer-generated querying of the features introduced here [475]. There is no need of once-for-all solutions or a priori optimization criteria. Hypermedia concepts can serve as navigation or explanatory aids [476].

Determination of Communications Costs. Field-level communications systems (i.e., field bus systems) will be essential components of a networked system. The design of future field bus systems will be based on the information economy derived from the phase model (Fig. 156). A suitable field bus system will be chosen on the basis of a taxonomy, here the taxonomy of field bus systems.

Typical message lengths for sensors and actuators, as well as maximum cycle times derived from the process and product properties,

Figure 156. Determination of communications costs

are balanced in order to arrive at the communications costs for the system as a whole. The number of field bus systems and the number of segments in these systems are set on this basis. The result is a picture of a CAE tool for the information-oriented design of communications systems [477]. The advantages of information modeling dictated by the process are again manifest here.

A proposal for a taxonomy of field bus systems is shown in Figure 157 [477]. The generic attributes are architectural features and the communications structure. Monomaster systems have a pure master/slave structure with strictly hierarchical vertical communications between planes. Multimaster or peer-to-peer systems, in contrast, permit horizontal communications within a plane. For the wastewater treatment example of Figure 151, both monomaster structures within a plant section and multimaster structures for communications between plant sections are possible. Communications between local components and sensors (e.g., pH and flow sensors) within a plant section might be based on the PROFIBUS or the DIN measuring bus, while communications between plant sections and with higher-level central functions might be implemented on the basis of PROFIBUS.

General Requirements on Process Sensor Systems. A complete introduction to process sensor system technology would also cover selectivities, detection thresholds, time dependences, sensitivities, stabilities, and so forth, all qualities that have to be defined for each sensor system [442, 478]. These are technical specifications that differ from one measurement task to another because of differences in service conditions, products, perturbations, and so forth.

The profile of requirements on sensor systems is strongly influenced by the downstream computer processing of the information:

- In-line and ex-line sensor systems must not disturb the process.
- It is essential to separate the energy channel from the information channel.
- Communications capabilities and system capabilities must be insured.
- Electromagnetic compatibility is also required; in some cases, external constraints dictate “intrinsic safety” as well [386]. See the generic class “Design Features.”
- Special conditions in chemical production (corrosion, abrasion, etc.) must be taken into account when choosing the sensor principle and construction material.

Figure 157. Taxonomy of field bus systems [477]

– One special requirement for in-line sensor systems is that they must remain functional even under extraordinary process conditions (e.g.,upon a change in the state of aggregation).

Economic Aspects. From the standpoint of the process control engineer who designs, commissions, and maintains a sensor system, meeting the stated requirements is closely linked to the lifetime costs of the sensor system. The term "cost of ownership" expresses the fact that the key criteria include not only the technical specifications and the resulting investment costs, but also longer-term aspects of sensor system use, such as training and maintenance costs. As discussed in Section 2.1, a holistic approach [479] must be taken from the outset.

In general, however, the main stress should be on the need for a process control station and a process sensor system. Total costs for a process monitoring and control system are largely determined by this sum. What is decisive is not the initial cost of devices and systems; the field installation costs make up a respectable fraction of total costs (see Section 10.2 and Fig. 320). Finally, the costs of control system components depends in part on the number of process control stations.

Often a fear of safety aspects and regulations leads to an exessive number of process control stations being set without a careful and critical analysis of the necessary equipment availability (Section 10.4).

Inadequate knowledge about the process at the time when costs are determined can, on the other hand, result in too few process control stations or incorrect equipment selection. This problem often cannot be corrected until commissioning, by which time costs are very high.

The departures from the original design may give nonspecialists the impression of "overengineering," especially if process control engineering resources must be used to correct solutions that are nonoptimal to poor from the process engineering standpoint. Overengineering due to ignorance is the most common cause of this phenomenon.

It is therefore essential that some tool such as the phase model of Figures 36 and 37 be employed at the bidding specification stage, in order

to take full account of all information needed for the production process.

5.3. Sensor Systems for Special Applications

In accordance with HESSE's suggestion [394] to put systems concepts at the beginning, Section 5.1 deals with systems integration of sensors or sensor systems, while Section 5.2 discusses process sensor systems from the standpoint of internal information flows and the taxonomies derived therefrom.

Nevertheless, it is necessary to descend from the lofty Olympus of informatics to the lowlands of the reality that must be dealt with at a pragmatic level.

Sensor systems behave very differently in the laboratory and the plant (see Section 5.2). The tasks they must perform, and therefore the requirements they have to meet, vary from one application to another.

Sensor Systems in Manufacturing [480]. For example, a sensor system in a manufacturing industry must provide an industrial robot with information about its surroundings that are relevant to the operation but not predictable. The robot must be able to react to this information in such a way that the desired result is achieved or maintained automatically. This is why a variety of sensors are employed to determine physical quantities and states, transform them into (generally) electrical signals, process them, and interpret them.

As a rule, information transmitted to the robot influences

- The position and orientation of the robot's manipulator or tool
- The speed at which it moves
- The execution of the program

In rough terms, sensors of interest for the field of industrial robots can be classified into

- Tactile sensors
- Noncontact sensors

Another principle of classification is the complexity of the information acquired, allowing sensors to be grouped into

- Sensors that transmit binary signals
- Sensors that transmit one-dimensional measurements (forces in a preferred direction, distances)
- Sensors that transmit multidimensional measurements (forces of arbitrary orientation)
- Sensors capable of pattern recognition (workpiece identification)

Figure 158 shows a taxonomy based on these criteria.

Under each of the categories cited, a number of functional principles can be employed, depending on the prevailing boundary conditions (Fig. 159).

The linking of robots to image-processing, pattern recognizing sensor systems and to tactile, multidimensional force and moment sensors is an especially urgent problem for future robotics applications.

Important future applications that can be exploited only with the aid of powerful sensors for industrial robots include

- The machining of workpieces
- Assembly
- Emptying of containers
- Continuous joining operations such as welding and seam cementing

The emptying of containers is a typical application for imaging sensors, which have the task of identifying workpieces in the container, measuring their orientations and positions, and providing the industrial robot with the information required to grasp the workpieces correctly.

The areas of machining and assembly are important applications for tactile sensors.

One task that illustrates significant problems and requirements in connection with industrial robots is machining with tolerances specific to the tool, the workpiece, and the robot.

If the tolerances and deviations exceed a certain value, it is no longer possible to achieve satisfactory machining results within a series of workpieces. An optimally designed, and therefore workpiece-variable, control of the machining process is only possible if the most important toleranced quantities are determined by sensors and the process is automatically optimized.

SCHWEIZER and WARNECKE distinguish two groups of variables: technological variables oriented to the machining process, such as power

Figure 158. Taxonomy of sensors for manufacturing

Figure 159. Distance measuring systems for industrial robots [480]

consumption and cutting forces, and geometrical variables such as tool wear, geometrical and clamping tolerances, and surface quality. The fundamental problem in such tasks lies in the high data rate and the mathematically demanding simulation process. Adaptation to a variety of tasks also complicates this application, which most commonly involves highly dedicated sensor systems.

Artificial sensors cannot offer the capabilities and flexibility of human senses, but they can reliably perform single functions in manufacturing. A survey of approaches in the field of quality assurance through production metrology can be found in [481].

In assessing future sensor technology, it is useful to compare biological and technical sensor systems [392].

In many areas technical sensors can be made substantially more powerful than biological ones. Furthermore, the spectrum of technical sensors is broader; that is, there are technical sensors for a wider variety of physical variables than nature has provided for among biological sensors. For example, technical sensors exist that can detect high- and low-frequency electromagnetic waves, electrical currents, and electric field strengths.

With regard to preprocessing by the sensor system, however, nature is far superior to artifice. Technical sensor systems at present are designed chiefly to detect events in preplanned technical processes. Accordingly, they can be more highly specialized for the expected events. Thus the knowledge that a foreseeable process event has taken place often comes solely from the fact that the sensor has responded. Scarcely any preprocessing is needed; the sensor "speaks for itself." By the same token, however, the system loses flexibility with respect to unexpected events. And this flexibility is particularly important for biological sensor systems, under some circumstances more important than high performance of individual sensors. Biological systems are designed to be more universal, while technical systems are more specialized. This notion is expressed in the term dedicated systems.

Most biological sensor systems are more "intelligently" constructed than artificial systems: Preprocessing takes place in amazingly powerful processing systems, with the result that vastly many individual items of information acquired by many identical sensors are reduced to summary information in a process of "supersign" formation. It is hardly possible to imagine the demand imposed on the processing system, not just by "concept-forming" logic but also by the coordination of the many sensors in arrays. In the eye, for example, the sensor array of the retina comprises millions of cone and rod cells. Nature again and again offers a very impressive demonstration to technology, showing how flexibly such array systems can react to unforeseen processes of many kinds. The array principle is now being increasingly used in technical systems, specifically where sensors and information-processing systems, given the proper degree of miniaturization and economy, can be integrated to form "intelligent" systems. This incipient symbiosis between electronic sensor technology and the microcomputer is opening up new dimensions for an innovative potential that has scarcely been tapped before [392].

Sensor Systems in Medical Technology [482]. Sensor systems used in medical diagnosis and monitoring must meet different requirements.

The physician, in examining a patient, used to be dependent on what the patient and his relatives said, the physician's own experience, and above all his senses. Today, medical technology, developing in parallel with general technology, offers valuable help to the physician. The range of his sensory perceptions, in particular, has been hugely expanded by technical resources, sensors (i.e., technical sensory organs) playing an essential role. Milestones in this development include the discovery of X-rays by Roentgen in 1896 and the recording of a electrocardiogram by Einthoven in 1902. Procedures based on these techniques remain the cornerstones of clinical and practical diagnosis today.

The principal objective in the use of medical instruments is to support the physician in administering the optimal treatment to the patient. Important narrower objectives in diagnosis and monitoring are to acquire reliable diagnostic information, place the lightest possible burden on the patient, and hold the user's costs and efforts within reasonable limits.

Three areas of medical technology are especially dependent on sensors: imaging techniques [483], physiological measurements [484,485],

Figure 160. Diagnosis and therapy with medical devices [482]

and laboratory analytical techniques. In imaging and physiological measurement, the sensor is closely linked to the patient (Fig. 160); application aids or transmission media are also employed in many cases.

Only sensors and sensor systems with electrical output signals offer the possibility of instrumental processing, representation, and storage of information. A wide range of methods, drawn from a wide range of sciences, are available for the conditioning and interpretation of these signals; see, for example, the approach to dynamic entropy analysis in [486,487]. Nonelectrical sensors that are still of major practical importance include X-ray film and mercury thermometers and manometers.

The quality of the signals delivered by the sensor has a substantial influence on the value of the technical system as a whole. Often, no additional useful information can be derived from a poor output signal, no matter how extensive the post-processing. This consideration alone means that the effort of developing and maintaining sensors must be continued along with the work of applying them.

Imaging Techniques. Medical imaging techniques can reveal information that is not directly accessible to the human eye, either because of the nature and frequency of the radiation or because of the geometry of the body (Table 4). Except for thermography, these are active procedures; that is, the measurement is based on energy introduced into the body in the form of radiation or radiation-emitting substances. Additional contrast-enhancing substances are often applied as well. Crucial advances with regard to exposure time and image quality in some techniques have been achieved by using arrays (with many detectors working in parallel) instead of discrete detectors. Nuclear medicine employs as many as 60 photomultipliers; X-ray computer tomography (CT), over 2000 detectors; and ultrasonic examination methods, up to 200 piezoelements.

More recently, nuclear magnetic resonance (NMR) tomography has become an established technique. It has the advantage of using strong magnetic and high-frequency fields instead of ionizing radiation, so that the patient avoids the risks associated with radiation exposure.

Significant results can be anticipated from positron emission tomography (PET), which can be regarded as a symbiosis of nuclear medicine and computer tomography. This technique permits not only the three-dimensional determination of blood circulation in the brain, but also quantitative studies of metabolism. Together with single-photon emission computer tomography (SPECT), this procedure raises the hope that diseases in the future may be detected long before anatomical lesions or other symptoms develop [488,489].

Table 4. Sensors for imaging procedures in medical technology [482]

Imaging procedure	Sensor	Radiation
Nuclear medicine	scintillation crystal (NaI) + photomultiplier	γ-rays (radioisotope sources)
Classical X-ray (transmission image)	film + intensifier film ($CaWO_3$)	X-rays
	image intensifier	
	storage film (Ba halides)	
X-ray computerized tomography,	discrete scintillators (CsI)	X-rays
NMR tomography,	gas detectors (Xe)	
PET, SPECT	semiconductors (Ge, CdTe)	
Endoscopy	fiber optics	visible light
Thermography	thermofilm (liquid crystal)	infrared light (passive)
	bolometer	
	IR vidicon	
Nuclear spin tomography	HF antenna	high-frequency pulses, magnetic fields
Ultrasound:	piezoceramic	acoustic waves (MHz)
B display (realtime, compound)	piezofilm	
Transmission camera		
Transmission CT		
Doppler		

The images produced by nonelectrical sensor systems, such as X-ray film (with intensifying film) or fiber-optic endoscopy, can be electronically scanned for further processing.

Ultrasonic imaging presents a difficulty not encountered with other imaging techniques: the coupling of the sensor to the body. The contact must be made through a couplant having acoustic properties (impedance) similar to those of water or tissue; serious disturbances result from air inclusions.

Physiological Measurements. The task of physiological metrology is to determine time-dependent states and functions of individual organs and organ systems in the body.

In contrast to imaging techniques, the procedures in physiological metrology are mostly passive; that is, the signals acquired are chiefly mechanical and electrical signals inherent in the body. Quantitative results are needed in most cases. As a consequence, instruments used for temperature and pressure measurement in a medical setting must be calibrated against standards.

Parallels to process sensor system technology, with regard to nearly all application-oriented generic attributes (see Fig. 154), abound in this field.

In Table 5, important and characteristic applications are listed by groups of organ and the quantities measured. In addition, the relevant sensors and sensor principles are indicated. Further, the table indicates in what setting the techniques are used: D stands for clinical and practical diagnosis, M for monitoring (chiefly intensive monitoring), L for long-term diagnosis or monitoring under everyday conditions [490]. If a procedure can also be invasive, that is, if the sensor or parts of the sensor system are introduced into the body for the duration of the measurement or the body must be opened for the measurement, this is indicated by the letter I. Often information can be obtained only by invasive measurement; the decision is then based not only on the balance of benefits and risks for the patient, but also the cost of the sensor, which is influenced by more stringent requirements on quality and miniaturization.

In general, the following points are taken into consideration in the development and selection of sensors:

- Essential precondition: a satisfactory functional principle
- Reliable application with the least possible expenditure of time and materials for routine uses
- Compliance with national and international standards of technical safety
- Compatibility of materials, especially for internal and long-term use
- Resistance to a wide range of mechanical loads and chemical attack (contact agents, body substances, cleaning, disinfection, sterilization)
- Transportability and adequate shelf life under variable ambient conditions
- Economic mass production with reproducible properties

Robust sensors of simple design, which require no involved preparation or post-treatment, are advantageous; the increasing adoption of one-time articles is a direct consequence.

• Electrodes for Surface Potentials: One of the most frequently performed physiological measurements is studying the electrical activity of

Table 5. Physiological quantities and sensors listed by organ system [482]

Quantity	Sensor/ principle	Heart, circulatory	Respiratory	Gastro-intestinal, urogenital	Brain, nervous system, sense organs	Skin, connective
Force, acceleration	piezoresistive, piezoelectric, optical	D M ballistic cardiogram	D M respiratory mechanics, monitoring of apnea		D tremor	D M L motoric, weight
Pressure		D M L I blood pressure	D M respiratory pressure, resistance	D M I bladder pressure, uterine contraction pressure	D M I intracranial pressure, intraocular pressure	
Flow rate	optical, thermal, electromagnetic, ultrasound	D M I blood flow, pulse, stroke volume	D M respiratory flow, volume	D I urine flow, volume		
Sound	microphone	D heart sounds, Korotkoff's sounds	D auscultation	D intestinal sounds, fetal heartbeat	D hearing	
Temperature	thermal (NTC)	D M L integral quantity: body-core, skin temperature				
Electric potential, impedance	electrodes	D M L I EKG, rheogram	D M rheogram	D M fetal EKG, EMG	D M I EEG	D EMG
Magnetic properties	SQUID	D myocardiogram	D silicosis	D iron in the liver	D MEG	
Optical properties	photodetector			D amniotic fluid	D eye	D
Gases	electrochemical (polarography, potentiometry), spectroscopic	D M I O_2, CO_2, pH oximetry	D M O_2, CO_2	D I pH		D M I O_2, CO_2; tissue, transcu-taneous
Ions				D dialysis		D I
Organic substances		D I glucose enzymes	D alcohol acetone	D L		D I

* D = diagnostic use; M = monitoring; L = long-term diagnosis or monitoring; I = invasive.

organs by measuring electric potential differences at the surface of the body. The sensor system used to measure these low voltages (EKG amplitude ca. 1 mV; EEG amplitude ca. 50 μV) includes the electrodes and the electrolyte (each electrode plus electrolyte constitutes a half-cell) together with attachment agents, power cords, and connectors.

The criterion for choosing the electrodes and electrolyte is a well-defined, stable electrode potential with a low noise level. The time required to reach equilibrium after mechanical or electrical disturbances should be in the range of seconds, and the effect of imposed d.c. or a.c. currents should be slight (time-varying overvoltages, corrosion).

Electrolytes and adhesives should be skin-compatible; the electrolyte, as contact agent, must also lower the skin's electrical impedance at the point of the measurement.

For applications in which the required EKG quality is not too high, robust metal electrodes are frequently used. Where the requirements are more stringent or the conditions are more difficult (stress and long-term EKG, intensive care), the Ag – AgCl electrode is the only type employed. It is also the preferred electrode in ready-to-use one-time electrodes precharged with electrolyte.

• Sensors in Intensive Care: The principal intensive care sensor applications are in surgery and neurosurgery, cardiology, internal medicine, obstetrics/gynecology, and pediatrics. Typically the patient is connected to various diagnostic and therapeutic systems (e.g., infusion, respiration, dialysis) and also continuously attended. The sensors or probes attached to the body must not interfere with care and therapeutic measures and, conversely, must be affected as little as possible by these measures; sensors, instruments, and accessories must be as simple and reliable as possible.

A variety of designs are available for EKG, blood pressure, and temperature measurement in all fields:

- Ag – AgCl adhesive electrodes for adults and children, as well as for operations
- Blood pressure measurement by intermittent noninvasive means (cuff) or by continuous invasive means (catheter) with external pressure transducer
- Temperature sensors for body core or skin temperature

In addition, specific procedures and transducers are used in certain special areas, for example:

- Photoelectric monitoring of the peripheral pulse
- Monitoring of respiration in adults (thermistor) and in infants (rheographic, noncontact methods)
- Cerebral pressure
- Fetal EKG and contractions in obstetrics
- Monitoring of oxygen supply: CO_2 in respired air (by infrared absorption); transcutaneous measurement of O_2 and CO_2, chiefly in newborns

Sensors and their application must meet higher standards when used with infants, since all the bodily dimensions are much smaller than in adults and both risks and interactions must be more strictly avoided.

Invasive Measurement of Chemical Quantities: Except for CO_2 measurement in the respiration gas and transcutaneous measurement, the continuous measurement of substances involved in metabolism and other substances in the body has not yet become routine in intensive care medicine. Development of sensors for these purposes, especially in combination with catheters or for use as implants, has been going on for a long time; techniques known from the analytical laboratory, such as spectroscopy, polarography, and potentiometry, are in the foreground.

The use of specific membranes, electrolytes, and enzymes makes it possible to modify electrochemical sensors (oxygen and pH electrodes) for the measurement of other substances, such as glucose, CO_2, or ions.

The miniaturization of sensors and the mechanical and electrical connection of sensors to a catheter are tasks that have already been accomplished or are at least feasible in principle. Applications involving contact with blood have still not been satisfactorily solved, because in its properties and its interaction with materials, blood is probably more complex than any other fluid encountered in technology. The deposition of fibrin and other proteins in the sensor pocket has two consequences: an increased risk of thrombosis for the patient, and disruption of the primary contact surface for the measurement.

The routine adoption of new catheter sensors is also difficult because the station personnel must possess additional knowledge and capabilities, for example, in the operation and calibration of the instruments and in the assessment of the measurements.

Requirements as to the reliability and accuracy of catheter sensors are far surpassed by the requirements imposed on implantable sensors and sensors for controlled therapeutic procedures. Therapeutic systems controlled with chemical sensors are a topic of major interest for the future.

Promising applications for intensive care are respiration, dialysis, and balancing, for example the regulation of the water, electrolyte, and en-

ergy economy of the burn victims. Implantable devices for the delivery of medication, such as insulin delivery controlled by a glucose sensor, are a key area for long-term therapy.

The transition from the laboratory analyzer, still routinely used for this purpose, to catheter sensors has not yet been completed, even though the use of integrated circuits has already led to major advances in the direction of miniaturized and multiple sensors. The next step – to implantable sensors with long-term stability – may well be equally large. A contribution toward solving this problem may be anticipated from biosensors, in which integrated electronic structures are built and operated in direct contact with organic materials.

Sensor applications range from imaging systems to the invasive measurement of metabolic variables, with cardiological diagnostics and intensive care as points of emphasis. Metrological methods and application techniques merit special attention, as does the management of the patient – sensor interface.

A comprehensive literature survey can be found in [481]. Information on research projects in the methods and applications of microsystems technology can be found in [491], which contains a detailed bibliography, and [492].

Sensor Systems in Automobiles [493]. Automobiles today must satisfy increasingly stringent requirements for pollution control, economy, safety, and comfort. These standards can be met only with the help of electronics. Sensors are the essential link between physical, chemical, and technical processes in the automobile on the one hand and electronics on the other.

Sensors in an automobile must offer high reliability and accuracy in a harsh environment, together with small size and low cost. Costs for transmitters as used in process technology, where quantities are correspondingly small, range from a few hundred to a few thousand €(Euro); in contrast, the maximum long-term cost for many types of automobile sensors must be < € 5.

Classification of Sensors in Automobiles. The sensors needed in automobiles can be classified by use, characteristic curve, output signal type, and interpretation.

By Use:

- Functional sensors in drive-train control systems and in subsystems including the steering, braking, and body electronics.
- Sensors for monitoring and diagnostics, for example in the cooling, braking, lighting, fuel, and other systems.
- Sensors for safety and security purposes, for example in passenger protection, locking, and anti-theft systems.
- Sensors for information, for example in the measurement of fuel consumption and outside temperature, or in travel route monitoring [494].

By Characteristic Curve: Which of the following characteristics is preferred will depend on the sensor application:

- Continuous, linear: Preferred for systems that perform continuous measurements with a wide control or display range. Uniform sensitivity is desired.
- Continuous, nonlinear: Preferred for systems that perform continuous measurements with a narrow control or display range. High sensitivity over a limited range is desired.
- Discontinuous, limiting value: Used for state-dependent "program variation" in complex systems, for example to enrich the mixture when the throttle valve is full open and to monitor the critical limits in the automobile.
- Discontinuous, stepped: Suitable for monitoring components subject to wear where replacement must be planned ahead of time, such as brake lining replacement before a vacation trip.

By Output Signal and Interpretation:

- Voltage or current analog
- Amplitude analog
- Frequency analog
- Period analog
- Pulse-length analog
- Digital

Voltage and amplitude analog signals must be submitted to analog/digital (A/D) conversion before they can be processed in digital systems. Recently, however, inexpensive A/D converter circuits have appeared on the market in integrated form or partially integrated on a chip with the microprocessor. Integrated commuting circuits, known as multiplexers, make it possible to use these converters in a quasi-simultaneous manner for several pickups.

Time-varying signals such as frequency, period, and pulse-length analog signals have the advantage that they are not very sensitive to noise on transmission paths and they are easily digitized at the point of reception. The prerequisite, however, is that an appropriate converter circuit is located at the transmitter, because measured variables are not generally in this signal form. What is more, clocks and counters must be provided at the point where the information is to be processed.

Sensors with digital output signals have not been considered because of costs. The downward trend in price for integrated logic circuits, in particular microprocessors, has led to reconsideration of such new sensor configurations, in which microprocessors are included in the sensors. The resulting "smart sensors" offer marked advantages with regard to compensation of undesired variables as well as equalization; in some cases, A/D conversion can be carried out by the sensor itself. Code security procedures can insure reliable signal transmission, even in a noisy environment.

Requirements on Sensors

– Environmental Protection: Sensors used in automobiles operate in a hostile environment, being exposed to heat, cold, moisture, dirt, water spray, salt, electrical interference, mechanical vibrations, and mechanical shock. These factors make the measurement tasks immensely more difficult and represent a serious threat to sensor reliability and service life (Table 6).
  The most severe conditions are experienced by sensors mounted directly on the engine. A temperature swing from $-40\,^{\circ}$C to $+150\,^{\circ}$C and even around $800\,^{\circ}$C in the exhaust gas stream, as well as $100\,g$ accelerations, are common environmental conditions here, but components installed in the engine compartment also experience harsh conditions (Table 7).
  Whenever possible, sensors are therefore removed from the zones of most severe stress and installed at more favorable locations. For example, pressure sensors used to obtain the motor load signal are usually connected to the intake pipe by means of a hose.
– Reliability and Service Life: Reliability requirements for sensors on board an automobile are in all cases extremely high, but can be ranked as follows: safety functions, mobility functions, diagnostic and monitoring functions, and information. In addition to the needed reliability, there is often a further requirement that a sensor malfunction must also be detected so that the subsystem can switch over to emergency mode and permit at least a limited "limp home" function. Frequently this point has to be considered early in the sensor development process.
  As to service life, sensors must also fit in with the trend toward longer-lasting automobiles. Expected values are more than ten years or > 3000 h service.
– Accuracy: Although accuracy requirements in many instances are as high as those in

Table 6. Environmental influences on sensors and typical effects [493]

Environmental influence	Typical effects
Temperature/temperature change	aging, embrittlement, fatigue, cracking
Atmospheric humidity (with dew and fog)	stray currents, surface and contact corrosion
Precipitation (rain, snow, ice, frost)	electrolysis, swelling
Pressure (air, water)	function
Sand, dust	stray currents
Sunlight	ageing, cracking
Aggressive substances (NaCl, SO_2, H_2S)	surface and contact corrosion
Mildew	stray currents
Salt water and sea mist (road deicing salt, coastal areas)	electrolysis, contact and surface corrosion
Sulfur dioxide (industrial regions)	surface corrosion
Ammonia, perspiration	creep due to stray currents, loss on insulating resistance
Fuel and fuel vapors	surface corrosion, swelling
Brake fluid	surface corrosion, swelling
Battery acid	surface and contact corrosion
Motor oil	swelling

Table 7. Service conditions of sensors installed in the engine compartment [493]

Mechanical	
Vibrational acceleration	(potholed road)
	chiefly stochastic
	chiefly low-frequency (max. 10 – 30 Hz)
	effective (time-average) value: 5 – 25 m/s^2
	max. peak acceleration: 50 – 80 m/s^2
Climatic	
Temperature	normal 120°C; extreme 140°C
Max. humidity	38°C/95 % R.H.
Salt fog	24 – 96 h (DIN 50 021), depending on packing density
Water	splash to flooding
Dust and sand	density up to max. 5 g/m^3
Chemical	gasoline/oil vapors, alkaline cleansers
Biological	mildews and molds

process plants, this accuracy has to be attained at much lower cost. This can only be achieved by mass production in a highly automated manufacturing process. Because the required accuracy is generally the main factor governing selection of sensor principle as well as cost, it is important to take great care in determining the acceptable error. Excessive requirements have a superproportional influence on cost. Accuracies of 2 – 3 % are needed for many applications.

– Space Requirement and Weight: The trend toward smaller and lighter automobiles, dictated chiefly by fuel economy, means that components have to be made small; accordingly, there is often little space available for the installation of sensors. Lightweight, space-saving sensor designs are therefore preferred. Small sensors, furthermore, have the advantage that they experience smaller accelerations due to vibration and impact and thus are less prone to malfunction.

Quantities Measured in an Automobile. Despite the wide range of electrical and electronic systems used in automobiles, the number of physical quantities measured by sensors is limited. The most frequently used sensors are those measuring distance, angle, rotation speed, pressure, and temperature.

Less common but still important are sensors for flow rate, acceleration, force and torque, partial pressure, and humidity.

Even though the list of quantities is not long, a considerable variety of sensor types are employed because of the diversity of media (streams) measured, measurement ranges, required accuracy, and environmental standards. Two examples are given below:

– Engine Electronics for Gasoline Engines: Fuel injection and ignition must be controlled jointly and matched to each other. In other words, every operating condition must be identified and serve as input to the process of fuel metering and ignition timing. This results in following improvements: increased fuel economy, increased engine power per unit of displacement, and reduction of pollutant levels in the exhaust.
  The motor-electronics system needs sensors for engine speed, crankshaft position, air flow rate, air and engine temperatures, and intake pipe pressure (load signal). To insure compliance with stringent exhaust quality regulations, the system is augmented by a λ control with a λ probe. Other possible functions of the electronics include automatic transmission control, idle speed control, knock prevention, and exhaust recycling.
– Electronic Control of Diesel Engines: Diesel engines have traditionally featured mechanical control, but stricter air pollution and noise emission standards as well as demand have led to greater use of electronics. Figure 161 shows the process properties involved in optimizing a diesel engine along with the required sensors. Apart from the parameters listed above (e.g., rotation speed, temperature, pressure, and flow rate), quantities such as the beginning of injection at the nozzle and accelerator pedal position are measured.
  The example of the sensor detecting the start of injection illustrates how harsh some of the sensor service conditions are. This pickup is directly integrated into the nozzle holder and is thus in the immediate vicinity of the combustion chamber.

Measuring Principles of Automotive Sensors. The technical implementation of sensors for automotive service can be based on a wide range of physical effects (Table 8).

Table 8. Technologies for automotive sensors [493]

Quantity measured	Sensor principle and sensors
Distance/angle	short-circuit ring or disk potentiometer
Rotation speed	galvanomagnetic effects (Hall, magnetoresistive)
Pressure	piezoresistive semiconductor pressure pickups
	diaphragm unit with Hall, thin-film strain gage, or capacitive pickoff
	thick-film pressure pickup
Temperature	thin-film metallic sensors
	semiconductor (Si) sensors
Flow rate	heated wire or film
	propeller (fuel)
	circulating-ball sensor
Acceleration	spring/mass system with strain-gage (cast film, thin-film) pickoff
	piezoelectric sensor
	piezoresistive semiconductor sensor
Torque	magnetoelastic sensor (torductor)
	eddy-current sensor
	optical sensor
Oxygen concentration	O_2 concentration probe with ZrO_2 solid electrolyte

Figure 161. Process properties for optimization of a diesel engine [493]

Coating techniques are used in temperature sensors (e.g., Ni, Pt), strain gages (e.g., Ta), and rotation speed sensors (e.g., Permalloy).

The constant-resistance heated-wire sensor is used to measure air flow rates. The requisite long-term stability is imparted to the platinum wire by special surface treatment plus regular "refining."

Torque sensors would be useful especially in generating a load signal for electronically controlled automatic transmissions. The torque on the main shaft might be measured, for example. Because the shaft cannot be split, its elastic deformation can be exploited for this purpose. The eddy-current damping principle has proved suitable here. Two metal cylinders with lengthwise slots are slipped one over the other in the axial direction, with a clearance of about 10 cm, and rigidly attached to the shaft. When a torque is applied to the shaft, the cylinders rotate relative to one another. A high-frequency coil placed axially over the cylinder housings experiences unequal degrees of damping as a result.

Continuous acceleration sensors (accelerometers) are used for prompt collision detection so that passive passenger-restraint systems such as an airbag or belt tightener can be triggered. Spring-and-mass systems are a proven type of accelerometer; they are mechanically damped by being operated in silicone oil. A triangular leaf spring, preloaded in one direction, bears a mass at its free end. The inertia of the mass causes flexural loading of the spring in a roughly uniform manner, so that the spring is deflected accordingly. The flexural stress is detected by strain gages, which can also be thin-film devices.

In order to meet exhaust regulations and minimize pollutant emissions, the engine should be supplied with an air/fuel mixture as close as possible to stoichiometric ($\lambda = 1$), so as to insure proper functioning of the downstream catalysts.

Exhaust probes or λ probes permit accurate measurement of the oxygen content and regulation of the λ ratio. These probes have a characteristic curve such that even small departures from $\lambda = 1$ results in a very marked change in the voltage signal. For engines operated over a wider λ range, partial-pressure probes with continuous characteristics are in development.

The situation in the automotive sensor field can be summed up by saying that much has been achieved already but much development is still needed to reach further goals with regard to economy, safety, and exhaust cleanness with the aid of complex system concepts and electronics.

Above all, ways must be found of resolving conflicts between the objectives of performance and cost. One approach involves sensor technologies that offer major economies when put into mass production. The clear favorites at present are semiconductor and thin-film technologies. However, functional packaging, contacts, electronic interpretation, etc. account for a large fraction of sensor costs and largely determine performance and reliability. For these reasons, the industry must not simply further develop but must also invest in the development of these incidental technologies.

Sensor technologies of the same type, strongly oriented to specific requirements, are encountered in rail-mounted vehicles, ships, and aircraft. These application areas cannot be discussed further here.

Sensor Systems in Solid-State Process Engineering [495, 496]. Solid-state processes offer a further example of the relationships between product properties and process properties (as described in Chapter 3 and Section 5.1), especially with regard to quality assurance standards. The properties of disperse solids are influenced by the chemical composition and the physical state of the product (property function). For development, manufacturing, and use, it is necessary to know how the product state affects the quality attributes. Because quality attributes are determined on the end product, the characterization of the disperse state must be utilized in controlling the process. An important principle of quality assurance is that quality must be definable and thus inspectable. Metrology thus occupies a central place in quality assurance. The practices involved in quality assurance are oriented to the following steps, each of which contains specific problems for disperse products:

- All desired quality attributes are set forth in the profile of requirements
- The process must be structured
- Process control variables must be determined; property functions and modeling are particularly important here

Solid-State Processes. A solid-state process is a sequence of process elements put together in various combinations so that a solid with certain properties is created as the end product. A typical process sequence [497, 498] is shown in Figure 162 in terms of the phase model. As shown in Chapter 2, the phase model contains not only process elements but also the respective product states, and thus takes account of the way the product state changes in the course of the process.

Figure 162. A typical solid-state process: process elements and product states [495]

After a chemical reaction, the solid is formed by crystallization or precipitation. It is separated from the liquid phase in a mechanical separation stage, such as filtration, then washed, and finally dried in a thermal operation. A confectioning step may follow, in which the product is put into the form offered for sale. Confectioning may include the unit operations of size reduction, agglomeration, mixing, or fractionation. The end product must ultimately be conveyed, stockpiled, packaged, or metered. The product state changes after each process element: from solution via suspension and filter cake to powder or granular form (depending on the drying or confectioning step). An important feature of the solid-state process is that the product properties do not depend just on the chemical composition but also depend heavily on the disperse properties of the product.

RUMPF treats this dependence of the technological properties of a product on the physical properties by introducing the property function [499]:

Technological property =	f (physical property)
	$Q_i = f\ (E_{\mathrm{p}\,i})\mathrm{E}_{\mathrm{i\ chem}} = \mathrm{const.}$
Technological properties Q_i	Physical properties $E_{\mathrm{p}\,i}$
Processing $Q_{i\,1}$	Dispersity properties $\mathrm{E}_{\mathrm{p}\,i}$
Filterability	Size
Formability	Shap
Agglomeration behavior	Porosity
Application $\mathrm{Q}_{\mathrm{i}2}$	
Activity	
Action	
Instantaneous property	

Property functions apply to the sequence of process steps (processing properties) and also to the end properties, that is, the quality of the product (application properties). In filtration, for example, the fineness of the product is crucial; in the case of an automobile, the color properties depend in part on how finely divided the pigments are.

The product state is not only crucial to the end quality but must also be considered for each process element in solid-state processes. Not only does the product state change in each process element, the product state itself significantly influences the process element. A knowledge of how the quality attributes depend on the product state is essential for the development, manufacture, and use of products. Structuring of the process into units (unit operations) or meaningful areas is necessary if hold points with intermediate goal values are to be defined. These intermediate targets must be checked with appropriate methods of measurement, as a means of early process monitoring. The state of the end product is not simply established in the last process element; every process element throughout the process contributes to it. For this reason, close tolerances must be maintained even in the intermediate stages if the subsequent stages are to remain in the correctable range. The following steps must be considered from a quality assurance standpoint:

- Establishing the quality levels in the profile of requirements
- Structuring the process and identifying the process control variables
- Insuring the reproducibility of the process
- Optimizing the process

The various types of product quality target values are listed below for the example of pigment manufacturing:

Application properties
- Color strength
- Color coordinates
- Purity

⋮

Processing properties
- Pourability
- Freeness from dust
- Dispersion hardness
- Gloss
- Interfacial properties
- Rheological properties

⋮

Safety
- Low content of side products
- Easy to dispose of
- Nontoxic
- Incapable of dust explosion

⋮

Efforts must be made to achieve a number of quality attributes, and these target values relate not just to the final quality (characterized by the application properties) but also to processing properties (see Fig. 397), environmental aspects, and safety considerations. All these quality attributes must be monitored (i.e., measured). Two examples indicate how difficult this is.

Suppose that a paint, for example an auto body paint, is to be manufactured from a combination of pigments. The first substantial problems arise in the testing of tinting strength, since this measurement cannot be performed on a dry pigment. In practice, an entire paint factory must be "simulated" before this test can be performed; in other words, a procedure similar to that in the paint factory must be followed on a laboratory scale (Fig. 163). The test preparation must be done in the same medium, in the same technical facility, and with the same energy expenditure as would be used by the paint manufacturer; the paint must be applied by the same technique; and the same instrument must be employed for color measurement.

Figure 163. Process for manufacturing a paint, from the pigment to the painted surface [495]

All these requirements for pigment quality inspection cannot, of course, be satisfied when the pigment is to be used in paint for several users. Instead, from the test in one system, in one apparatus, and so forth (representative testing), deductions must be made about the behavior in other types of apparatus. The development of tinting strength in two unlike dispersion machines illustrate the potential problems of such deductions. In Figure 164, the tinting strength is plotted as a function of dispersion time. Unequal energies are applied in different dispersion machines, for example in a laboratory apparatus and the full-scale system. As a rule, tinting strength is determined after one or at most two dispersion times. The result is that the quality attribute "tinting strength" varies widely when the dispersion times and energies cannot be matched, or unambiguously correlated, with those of the user.

Figure 164. Tinting strength development for two dispersion energies [495]

This example shows what difficulties arise in quality inspection even when there is just one final target value. A process is designed and optimized for the final target values of a product, and the aim of quality assurance is to maintain these final target values. A standardized testing method leaves open questions of product quality for any individual case. Every user, however, wants a suitable pigment for its own formulation, where "formulation" or "recipe" covers both the paint system (including additives) and the apparatus and operating conditions.

Property Function. An important, necessary, but not sufficient step in quality assurance is quality control. As a rule, quality attributes are measured only on the end product. Thus quality can be controlled but not assured. Assurance, in the sense of "controlling," requires some way of influencing the process, and doing so at the earliest possible process stages. This in turn means that the process must be structured into single steps or meaningful subdivisions and that intermediate goals must be defined or established. These intermediate goals are suitable for early process control. The phase model (Fig. 162) and the property functions become especially important for quality assurance. Only when the relationships between quality attributes and physical quantities (property functions) are known is it possible to identify an appropriate process control variable. If the disperse state can be measured and controlled at the point where it is gen-

erated or changed, intervention in the process steps can be implemented at the proper time and thus quality can be controlled. In other words, a knowledge of the property functions is a prerequisite for the assurance of the quality of disperse products.

In the example of colored pigments discussed above, some of the property functions are well known. Figure 165 shows the target value tinting strength as a function of particle size. For two or more distinct target quantities, a compromise is necessary. The desired particle size should already be established at the crystallization stage.

Figure 165. Property functions for a colored pigment [495]

The property functions must be known if crystallization is to be optimized with respect to the application properties. Each subsequent process step changes the particle size and the state of agglomeration [500]; that is, the generation of particles by crystallization should be controlled and changes later in the process should be avoided or monitored.

The dispersity values based on the property functions are important control variables and thus make it possible to implement early process control. To determine the property functions, both quantities must be known and measurable, namely the physical quantity (dispersiness) and the technological quantity (application or processing quantity). The problems that arise in the measurement of the latter are discussed in Section 5.1. The measurement of dispersity is the focus of particle-size measurement techniques. Some aspects of particle-size measurement will be discussed briefly below.

Examples of particle properties with corresponding test methods are listed below:

Particle size (distribution), agglomerate size (distribution)	diverse methods
Specific surface area	BET method
Flow behavior	shear test
Bulk density	determination of volume and mass
Compressibility	determination of volume and mass, force – distance diagram on compression
Redispersibility	transmission measurements PSD measuremens for various degrees of dispersion
Wetting, porosity	liquid absorption, capillary pressure

Generally, the particle size (primary particles up to agglomerates) and the particle size distribution are of fundamental importance for solid-state process engineering. A number of methods are available for their measurement. These have been described in many publications and analyzed with respect to time, costs, and problems [501,502]. The trend is toward measurement techniques and instruments that utilize the optical properties of disperse systems as a tool for characterization.

Instead of going further into individual measurement methods, the problems linked with the use of these methods is discussed here [503]; see Figure 140. As a rule, a sample must be taken from the process. (The special features of sampling of powders and granular materials have been thoroughly treated [504].) The sample must be transported to the measurement location and prepared so that the constraints imposed by the measurement technique can be complied with. Preparation may mean filtering or diluting the sample, cooling or heating it, dispersing it, or adding other substances to it. These measures, which can bring about a change in the product, transform the process state into the measurement state. Moreover, the time between sampling and result is often much too long. A measurement that does not become available until hours or even days after sampling is not useful for process control.

Thus the objective can only be on-line measurement [444] to obtain information on the product or process state quickly. Sample preparation must be automated so that the measurement state can be correlated with the process state in the most reproducible manner possible. Ultimately, however, in-line measurement (see "Generic Class: Application Features," page 135) must be employed to generate the required information about the process state. Two examples of new in-line methods of importance to solid-state processes are presented briefly.

- Laser scanners [505]: The particles are scanned with a laser and a chord – length distribution is obtained. The probe can be immersed in any vessel whose contents in are in sufficient motion ($0.01 \leq v \leq 1$ m/s). The particle-size measurement range is 1 – 1000 µm.
- Photon correlation spectroscopy [506]: In this laser technique, particle mobility is measured on the basis of Brownian motion. The Einstein relation links the stochastic motion with the particle size via the diffusion coefficient. This method is in successful use, for example for process characterization in vitamin production.

A comprehensive exposition of particle and particle-system characterization can be found in [496], which treats this topic within the framework of sensor system technology. Particle measurement, which extends far beyond the boundaries of particle-size analysis, is completely discussed as to status, trend, and demand in [507], which builds on ideas similar to those that underlie quality assurance in solid-state process engineering [508].

Sensor Systems for Environmental Protection. The prevention or reduction of environmental pollution caused by industry, commerce, agriculture, households, etc. requires not only technical measures but often also measurements, whereby process sensor systems (see Section 5.2) are used to provide the required information about the properties of the relevant product or process element, about water and air pollution caused, and also about noise pollution.

To enable quick reaction in the sense of environmental responsibility, and also as mandated by environmental legislation, the required information must be available on-line (see Section 5.2).

For this purpose it is especially important that information about the product properties be obtained in undistorted form. This can be achieved by measurements on the relevant product itself, performed in-line, that is, in the actual product stream. This is not a simple matter with many present-day sensor systems.

The special features of sampling (in comparison with solids sampling as discussed elsewhere in this section), with the aim of insuring spatial and temporal representativeness, are discussed further on.

Figure 166 shows, in highly simplified form, the tasks of process sensor systems in environmental protection. These systems acquire information about the product and process properties, measure workplace pollutant levels for occupational safety and health reasons, and monitor wastewater, solid and gaseous emissions in stack gases, and noise emissions for environmental protection purposes [509].

Flue-Gas Monitoring Sensors. By way of example, some of the requirements for flue-gas monitoring are examined for a coal-fired plant.

• Power-Plant Flue-Gas Monitoring: The German regulations on power station emissions require continuous measurements of the mass concentrations of particulates, CO, halogen compounds, NO_x, and SO_2, and also of the volume concentration of O_2 (Fig. 167). All instruments used must be tested for suitability; proper installation of measuring devices must be verified by services designated by the authorities; calibrations must be carried out every five years (plants with thermal power under 300 MW) or every three years (plants over 300 MW). In addition, unannounced functional tests are performed yearly.

The measured values (instantaneous values) are interpreted by

- Taking half-hour averages
- Taking daily averages
- Converting the averages to reference oxygen contents
- Classification of O_2-referred averages and storage in the form of frequency distributions

Pursuant to the regulation, the emission limits are deemed to be complied with if

Figure 166. Process sensor systems (S) in environmental protection [509]
A = actuator system; EP = environmental protection; OHS = occupational health and safety; PS = plant safety

- All daily averages are $\leq$1.0 EL (EL = emission limit)
- 97 % of all half-hour averages are $\leq$ 1.2 EL
- 100 % of all half-hour averages are $\leq$ 2.0 EL

Figure 167. Example of a fired facility [509]

A cross-reference to the concepts of human – process communication (Section 11.2) is relevant here. If compliance with the emission limits is also to be monitored by the operating personnel on behalf of the operator, the levels should be represented by means of suitable presentation and interaction forms. An example of such a form is a cumulative frequency chart updated on-line (see Fig. 168) [510].

Sludge Incinerator: Sludge from biological wastewater treatment is dewatered in filter presses and is then forwarded to a furnace for combustion. Such an incineration system includes a hot ("dry") stack gas scrub, which is subject to HCl and SO_2 controls (Fig. 169).

The emission measurement hardware is designed to comply with TA Luft. Emissions (concentrations) are referred to wet gas in the measurement stream, so that the content of water vapor must be determined each time. This is done directly on the basis of the measured O_2 levels in the wet gas (O_{2W}) and the dry gas (O_{2D}). The measurements are analyzed by averaging, referring to O_2, and classification. Instruments are calibrated by a service holding an official permit.

General Emission and Impact Monitoring of Gaseous Pollutants: Gaseous pollutants represent a special danger from the environmental and occupational safety and health standpoints.

Formerly, this problem could be handled only with expensive suction-type gas collecting sys-

Figure 168. Viewpoints, presentation, and interaction [510]

EF, electrostatic filtration; S, stack-gas scrubbing; HHA, half-hour average

tems, which delivered the mixture of pollutants to product-identifying sensor systems. Examples of such systems were spectroscopes, chromatographs, surface-sensitive metal oxides [511] and semiconductors, as well as physicochemical flame ionization detectors [512] and ZGSM gas detectors [513].

As described in Section 5.2 [386, 389], the sensor system proper then includes sample preparation, measurement, and application.

As early as 1985, WARNCKE [382] reported on optically integrating absorption measurements over long lines in the open atmosphere. The measurement of pollutant components in the infrared by this remote analysis technique is best performed with lasers. Rotating sensor systems place a "detection cone" around the object where emissions are expected to occur (Fig. 170).

By way of example, Figure 171 shows emission monitoring at a chlorine plant with an "an-

Figure 170. Continuous plant emission monitoring with rotating laser backscatter photometers [382]

alytical eye," an ultraviolet instrument using a conventional light source. The special innovation here is that the interference due to sunlight is compensated by using a pulsed light source. The source intensity during the pulse is much greater than that of the interfering light. Accordingly, in the detection range the aperture can be made small enough to prevent presaturation of the detector by the interfering light. If necessary, measurements can be performed at two reference frequencies to compensate for light scattering by particles.

This procedure amounts to setting up an optical enclosure around the whole production plant. Despite the use of modern lock-in amplifiers, the cross-sensitivity and relatively high cost of the apparatus has kept these developments from gaining wide adoption.

The current status of this process sensor system technology is surveyed by [514].

Wastewater Monitoring

- Monitoring of Combined Sewer Water: Much of the energy of reaction generated in a process is typically transferred to water (usually withdrawn from a stream) in heat exchangers. Along with storm sewer water, this cooling water is discharged directly into the receiving water through a combined sewer. Contamination can occur when rain falls on roofs, streets, and other areas containing pollutants; in the ordinary drainage lines; or through leaks in the heat exchangers.
- Process Wastewater Monitoring: All other water used in the plant, including scrub liquor from final cleanup stages, must be conveyed through the now-standard system (including mechanical, chemical, and biological treatment processes) in order to comply with legislative requirements.

Without going into detail on national and international laws and regulations governing wastewater, or on the legal consequences of a violation [515] (see Chapter 12), Figure 172 illustrates some aspects of the situation in Germany.

The new philosophy of international environmental protection declares the protection of natural waters from pollution to be a high good, regardless of whether the polluting wastewaters originate in households, public facilities, or industry. Accordingly, the availability of treatment functions in treatment plants is declared to be beyond the scope of economic discussion.

Raab and Wachter-Büchner state in particular [516]: "In order to comply with the legislative mandate, precautions commensurate with specific potential hazards must be taken. These include, first, technical precautions that reliably prevent contamination of the wastewater or the occurrence of severe pollutant burdens in the first place. An effective complement to these primary technical measures is continuous analytical monitoring of wastewater streams for substances foreign to water. In the chemical in-

Figure 172. German wastewater legislation and regulations [515]

dustry, many such substances are carbon compounds, which often means organic contaminants. The parameter TOC (total organic carbon), which states the total content of organic carbon in mg C per liter of water, has proved to be a highly suitable quantity to measure for this purpose.

Water monitoring is not, however, limited to the detection of undesired organic contaminants in wastewaters. Increasingly, it is also employed in process monitoring. Along with environmental protection applications, TOC measurement can also be found in production monitoring and control. A company has control of its production only if it also knows the makeup of its wastewater. A topic of recent discussion is the continuous measurement of TOC burdens in wastewater streams (balancing), which is a prerequisite for source apportionment of wastewater streams within a production complex.

Environmental protection regulations and production monitoring needs dictate the measurement mission. If it is taken seriously, this means the continuous determination of TOC. Only if wastewater streams are subject to continuous, on-line monitoring as near as possible to a potential point of entry of water pollutants can inadvertent contaminants be detected promptly and countermeasures put quickly in train. The monitoring of process wastes also requires continuous surveillance, whether to prevent overloading of the treatment plant or to promptly detect improper states in the plant. There is a definite trend toward process TOC measurement, that is, continuous 24-h determination of TOC in the wastewater. From the metrological point of view, this is not a simple task; from the instrumentation standpoint, it requires substantial expenditure.

According to DIN 38 409 Part 3 [517], TOC is the sum of organically fixed carbon in dissolved and undissolved organic compounds. The DOC (dissolved organic carbon), is the sum of carbon contained in dissolved organic compounds. Other terms in common use are TC and TIC. TC (total carbon) equals the sum of organically and inorganically fixed carbon in dissolved and undissolved compounds. The inorganic component of the TC is called TIC (total inorganic carbon). Each of these is expressed as a concentration in milligrams of carbon per liter (Fig. 173 [516]).

The basis for all methods used to determine organically fixed carbon in water is the oxidation of carbon to carbon dioxide. This can be accomplished in a thermal process (combustion), by wet chemistry (with suitable oxidizing agents), and/or by irradiation with ultraviolet light. The last method is restricted to solids-free samples.

The carbon dioxide resulting from oxidation is either determined directly or reduced with hydrogen and determined indirectly as methane. The determination can be carried out in the liquid or gas phase. Methods suitable for use in the liquid phase are photometry and conductometry. The most common technique, however, is

	mg C per liter in			
	organic compounds		inorganic compounds	
	dissolved	undissolved	dissolved	undissolved
TC (total carbon)	○	○	○	○
TIC (total inorganic carbon)			○	○
TOC (total organic carbon)	○	○		
DOC (dissolved organic carbon)	○			

Figure 173. Definitions [516]

to determine carbon dioxide in the gas phase by IR spectroscopy. For the TOC measurement methods in ordinary use, the individual process steps are summarized in Table 9 [516], together with the starting and end products of each phase transformation, up to the acquisition of the measurement.

Depending on the physical locations of the sensor systems and the way they are tied into the sewerage (process discharge, sewer junction, plant discharge, treatment plant), the requirements on the following performance features vary widely:

- Selectivity
- Detection threshold
- Time behavior
- Availability

Besides the carbon contents TC, TIC, TOC, and DOC, water quality is also determined by other product properties [515]:

Physical and chemical product properties
  Temperature
  Conductivity
  pH, redox potential
  Turbidity
  Contaminants from process
  COD
  pO_2
  Salt
  Ammonium
  Nitrate
  Phosphate
  Heavy metals
Biological parameters
  BOD_5
  Saprobic index
  Toxicity

The methodology of wastewater monitoring is shown in Figure 174 [515].

On-line instrumentation is available for the determination of most product properties. Such

Table 9. Steps in conventional TOC measurement

Process step	Starting/intermediate product	Phase transition	Intermediate/end product
I	organically/inorganically fixed carbon (in water)	separation inorganic/organic species	CO_2 (inorganic) + volatile organic carbon compounds (in gas phase) organic carbon (in liquid phase)
II	organic carbon (in liquid + gas phases)	oxidation thermal chemical photochemical (UV)	$CO_2 + H_2O$ + reaction components (in gas phase)
III	$CO_2 + H_2O$ + reaction components (gas phase)	measurement gas preparation (e.g., drying) absorption of CO_2 (in liquid reagent) reaction (hydrogenation of CO_2)	CO_2 (in gas phase) CO_2 (in liquid phase) CH_4 (in gas phase)
IV Analysis	CO_2 (in gas phase) CO_2 (in liquid phase) CH_4 (in gas phase)	selective IR absorption (photometry), color reaction/conductivity change (photometry/conductometry), combustion (flame-ionization detector)	TOC (mg C/L)

Figure 174. Methodology of wastewater quality monitoring [515]

fully automated devices take water samples, analyze them, and output measurements in computer-readable form in a continuous manner (or quasi-continuously in the case of cyclical analytical methods); see, for example, [518]. The spectrum of on-line measuring instruments that come under consideration ranges from robust devices proven over many years in process monitoring service to complicated and expensive special-purpose apparatus such as TOC analyzers (see above) and toximeters. Similarly broad is the range of performance features and costs for installation and maintenance of the measurement systems.

Representativeness in space and time merits special attention, since the products present in a plant wastewater system generally change from time to time, they are poorly mixed (in laminar flow), and if the pipes do not run full they do not reflect the actual product qualities. Furthermore, it must be ensured that no chemical reactions take place downstream of the sensor system that might lead to other pollutants that then remain undetected. The use of analytical instruments for wastewater analysis must always be examined from the standpoint of explosion hazard.

If there is no usable foreknowledge of the potential pollutants, measurement techniques of universal applicability must be employed; examples are TOC determination (see above) and flame – ionization detectors with phase changers. The apparatus is more expensive and cannot

always be installed in an explosion-proof manner; the selection of physical location may also be severely limited.

If instrumentation is present at the process discharge, expansion is possible by relocation aimed at bringing internal substreams under continuous monitoring. In this way the source of wastewater upsets may be localized [509].

Sensor Systems for Noise Pollution Control. The well-known instrumental methods of noise measurement cannot be treated in detail here, but for the sake of completeness a few remarks are offered from an applications standpoint.

The metrological tasks of noise pollution control in the environmental protection context include the following:

Noise level measurements in the vicinity for the determination and monitoring of noise contributed by the plant and by the surroundings, in particular by traffic.

Emission measurements to determine the level of noise radiated from individual pieces of equipment (acoustic power) and prepare an emission register (acoustic power levels of individual sources).

Calculation of impacts from emissions (noise radiation), with allowance for propagation damping between source and test point, to prepare an impact register (acoustic pressure level in the vicinity).

Comparison of measured and calculated impacts (levels) to validate the level mesurement technique or the propagation damping law used in the calculation [509].

In the framework of the occupational safety and health effort, these tasks are extended to the workplace proper. The large volume of interpretations require sensor and computer systems that are matched from an information-technology standpoint.

Sensor Systems in Polymer Production. In principle, the same problems arise in establishing the product properties throughout polymer production as are discussed in Section 5.1 [406], in Section 11.3 (process analysis and optimization aspects), and specifically in this section [495, 507].

Like all production processes, polymerization can be represented in terms of the phase model (see Chapter 2 and Fig. 175).

Figure 175. Material and information flows for production of a chemical material [391]

Determination of Relevant Product Properties throughout the Process. The first central problem in determining the product properties is that the properties established or required in the end product (elements of the requirement profile) cannot generally be represented after all the prior steps in the process (see Fig. 35); for example, even a change in state of aggregation makes it necessary to examine more than just one category of these product properties.

Determination of Relationships between Process and Product Properties. The second group of problems arises because the relationships between the properties required in the end product or technological application (requirement profile), the actual product properties (qualification profile), and the properties that exist in the prior stages of the production process are not directly known. Rumpf first discussed this question from the standpoint of experience with solid-state processes (see above), coining the term "property function" for these relations [499]. Later, Ecker et al. applied terms such as "process indicators" to similar solution approaches [406]. Here, as discussed in Section 5.1, the relationship between "technological" [386, 391, 406] and "physical" product properties was formulated. In acry-

Figure 176. Scheme of HPLC methods [523]

lonitrile polymerization, for example, a viscosity quantity is often used as a control variable (K value) [519–521].

Relaxation Time of Product Properties. The third set of problems is due to the fact that important product properties cannot be determined online (see Eq. 5.2-1) because the mea-surement process has a relaxation time τ_{Rsens} (required for information acquisition) that is too long or fails to satisfy Equation 5.2-1.

In-Line Measurements. Another important aspect is that information acquisition, in its sensor-linked stage (see Fig. 145), often involves not the product itself (in-line, see Section 5.2) but rather an extract, usually prepared after being obtained by appropriate extraction of the product from the production events (ex-line).

Hotop and König have readdressed this problem with application to polymer processes [522].

Complex Shear Modulus. The product properties (chiefly the mechanical-technological ones) can be described by the complex shear modulus G^* (see Section 5.1). This "phenomenological" quantity, which statically and dynamically describes the reaction of a product when a mechanical field acts on it, affords a key with which the mechanical behavior can be traced back to elementary molecular motions, provided there is an adequate theoretical framework. Kuhn [410] and Pechold [411] carried out useful preliminary work, which Morbitzer et al. [412–414] has developed to the stage of practical application.

Molecular-Mass Distribution. The macroscopic mechanical behavior of polymers is essentially governed by the chain-length distribution or molecular-mass distribution and by the degree of cross-linking. A variety of HPLC methods are used here (Fig. 176 [523]).

Only when, as discussed above, there is a stable relationship between the molecular properties of the "process product" (in-line) and extracts rendered "measurable" through a series of differential-solubility operations (ex-line) can the conclusion stated above be justified (see also [524]).

In any case, a specific relation and a specific model must be sought for each application, so that process control consistent with quality assurance can be implemented. From a modern information-oriented standpoint, all such efforts lead to measurement techniques associated with process indicators [406] or supported by models [432]. A comprehensive bibliography can be found in [390].

Purity Guarantee. Similar aspects must be considered for the second collection of tasks, the guarantee of chemical purity for intermediate and end products.

It is beyond the scope and aim of this article to describe material-identifying spectroscopic and chromatographic methods (see [434] for more details).

An illustration of these points is shown in Table 10 [522].

Sensor Systems in Biotechnical Process Engineering. In the preface to [439] Schügerl states that the most important difference between biotechnology and its predecessor, fermentation technology, is that fermentation tech-

nology is an assemblage of hard-to-quantify empirical relations, while biotechnology is an assemblage of relations that are still empirical but can be represented in quantitative form. The foundation has been laid for biotechnology to arrive at a point where it can make quantitative predictions with the aid of general laws. The same holds for both microorganisms and cell lines.

Table 10. On-line measurement tasks in polymer processes [522]

Measurement	On-line analytical methods	
task	Conventional	New
Mixture, purity, and trace analysis	density, refractometry, photometry, titrimetry, GC, photometry after color reaction	spectrometry, liquid chromatography
Additives		
Side components		
Residual monomer		
Polymer		
End groups		
Molecular mass determination	viscosity, light scattering	gel chromatography
Average molecular masses		
Molecular-mass distribution		
Chemical constitution as function of molecular mass		
Characterization of polymer melt/commercial product	rheometry, photometry	spectrometry
Additive content		
Rheological properties		
Branching, cross-linking		
Chemical composition		
Residual solvent content		

Previously, production strains were always selected by tedious screening and then laboriously improved by induced mutation and screening. Today, these strains are increasingly being modified to order by using genetic engineering. Protein design makes possible the purposeful local modification of proteins through appropriate genetic modification of the microorganisms or cells. Metabolite design allows the metabolic pathways detrimental to production to be eliminated and desired pathways to be reinforced.

Analytical techniques play a key role in the industrial exploitation of the full biological potential of the microorganisms and cells obtained in this way. These techniques make possible a precise study of the cell physiology and allow quantitative determination of the regulation of the metabolism. Furthermore, the optimal process conditions for growth and for product formation can be brought about and maintained by means of process analysis.

The same rules apply here as for the other fields discussed in this section, though at a high level of abstraction; see the discussions of solid-state process engineering and polymer production engineering above, as well as Figures 125 and 126.

Sensor systems commonly used in biotechnical process engineering [440] are as follows:

On-line and in situ fluorimetry
- NMR spectroscopy
- ESR spectroscopy
- X-ray structure analysis

Chromatography
Mass spectrometry
Electrophoresis
Optical and acoustic microscopy
Flow cytometry
Flow injection analysis
Bioelectrodes
Biosensors
- Biocalorimeter
- Bio-FETs
- Piezoelectric biosensors
- Optodes

Antibody/antigen systems

Along with the classical methods, which are known at least in general principle in chemical process engineering, a new class of sensors are now appearing: biosensors, which are used especially to mesure specific biological product properties (see Fig. 152). In these sensors, only specific biological reactions yield a sensory effect.

As a rule, however, parallel, serial, or associative linking of information is used [382]. A typical example is given by fermenter analysis (see Fig. 177): The following specific items of information are available: pressure, flow rate, and oxygen content of inlet air; oxygen, carbon dioxide, and nitrogen content of outlet air; pH and turbidity of the solution; and contents of oxygen and carbon dioxide dissolved in the solution. A calculation relating the oxygen and carbon dioxide concentrations to the air through-

put (Fig. 178) gives the respiratory quotient as the ratio of oxygen uptake rate to carbon dioxide evolution rate. Together with a knowledge of the mass-transfer coefficients from the gas phase via the liquid phase to the cell, this makes possible an optimization of the air throughput at a higher level of assessment [382].

Figure 177. Measurements in fermentation [382]

As shown by Warncke [382] and Hotop and König [522], the greatest difficulty in biological product property determination lies in sampling and sample preparation, which must be done case by case. Without the aid of robotics in sampling and sample preparation and without information-oriented model support, sensor systems in biotechnical process engineering would be inadequate.

Additional constraints include foreign influences and the disposal of sample material after the measurement (see Fig. 144).

Biology itself, however, must increasingly become the guide in the development of biosensors. Multisensors, sensor arrays, and the processing of many simple signals in a manner similar to the neuronal structure of organisms should provide the solution to many problems [392].

Interesting results in the identification of process trends have been obtained by Adler [525], who used fuzzy clustering methods, which Winterstein has tested in practice by applying a multivariate sensor system to wastewater monitoring [526].

Outlook. In order to control a production process, it is necessary to look at information on various levels (Fig. 179). Sensor and actuator systems link the process with the information processing. Process monitoring and control systems take on the function of information processing and human – process communication.

The information orientation of process control engineering means that proven measurement techniques must be developed toward a sensor system technology.

The necessity of providing interpretable information to the process monitoring and control system at any time means a change in the requirement profile for sensor systems of the future:

- Reliability at reasonable maintenance cost
- Functionality even in extraordinary process states (e.g., startup, shutdown, upsets)
- Adequate accuracy and predictive power
- Easy adaptation to production variation [527]

Self-diagnosis and self-maintenance are important qualitites of future sensor systems. The information structure of a universal sensor system is illustrated in Figure 145.

Figure 178. Gain in information due to coupling [382]

Figure 179. Sensor systems in the information chain from material/energy flow to human – process communication

Increasingly, manufacturers face the challenge of designing modular, engineered sensor systems. Design, together with easy installation and maintenance, represent untapped potentials for improved efficiency.

Of course, there are not yet any adequately tested sensor systems for polymer and biotechnical production, for the solid and suspension states of aggregation, and for many areas of environmental technology. Essentially, however, it is more important to bring the classical (physical, chemical, and technological) measurement techniques up to the new standard.

Hauptmann calls for the following among other points [528]:

"In order to develop sensors and bring them to market at low prices, some fundamental requirements must be met:

- Precise knowledge of the market and of international development projects as a basis for innovation
- Concepts, strategies, and visions of future sensor markets and technologies as a basis for long-term success
- Strategic partnership and cooperation with research institutes, universities, users, and manufacturers"

There is a clear trend away from the laboratory towards the process environment [382, 514].

Already, under the auspices of ISA, IFAC, VDI/VDE-GMA, and other organizations, numerous forums are available worldwide for the discussion of sensors, sensor systems, technologies, and applications.

These discussions, often academically conducted, are brought down to earth by applications-oriented conferences such as GVC, the Eisenhüttentag (Foundry Conference), and NAMUR, which deal with the harsh conditions of everyday service (see above).

With increasing success, attempts are being made to bring structure into this unbounded variety by using new methods of applied informatics [529] and to find routes for effective application through hypermedia (see Fig. 154).

Nevertheless, the need to set down in-depth knowledge in encyclopedias [530] will still exist, so that this knowledge can be kept up-to-date (with a view to the taxonomies cited above) through supplementation or modification of the assignment of object attributes.

Special sensor technologies are continually being reported on by technical and scientific journals such as TM, IFAC, ISA, and atp. These include:

- Optical sensors (including fiber optics)
- Chemical sensors, such as
  - Liquid electrolyte sensors
  - Solid electrolyte sensors
  - Mass-sensitive sensors
  - Optochemical sensors
  - Calorimetric sensors [528]
- Surface-active metal oxide and semiconductor sensors
- Biological sensors

Four general trends can be identified:

Advances in Existing Sensors. The development of existing sensors and the creation of sensor systems continues. Multisensor systems based on commercial sensors, coupled with new signal recognition and signal processing techniques, will open up new application areas. An important aspect is the modeling of the sensor with regard to the effect measured as well as parasitic effects. Pattern recognition in forms ranging from classical to fuzzy logic will promote this development.

Digital Sensors. The resonance sensor is an important step toward digital sensors. This class includes micromechanical resonant sensors as well as sensors based on piezoelectric materials. Analog sensors can be replaced by resonant detection mechanisms with no change in sensor configuration. The coupling of resonant structures with fiber-optic excitation, detection, and signal transmission will increase. The development of entirely novel sensor principles will largely remain an exception.

New or Modified Sensor Materials. Material development is currently a major theme in sensor development. An important role is played by polymers, ceramics, composites, alloys, biomaterials, modified glass-fiber materials, III – V semiconductors, and so forth. Silicon, however, will remain dominant and combinations of silicon with other materials will be increasingly used.

Microsystems. Microsystems technology is having a lasting effect on the field of sensors. A microsystem is a spatial integration of sensor, signal processing, data processing, and actuator. This technology combines methods from microelectronics, micromechanics, microoptics, and information technology. It even makes use of techniques from acoustics, hydraulics, chemistry, and biology. It includes the design, fabrication, and application of technical systems that integrate a variety of functions. The functional units of a microsystem interact closely with one another, and their geometrical dimensions, dictated by functional considerations, are typically in the range from millimeters down to micrometers. An essential criterion for the design of microsystems is optimization of the overall function. This is advantageous from the standpoint of technological effort, because it is not always necessary to optimize the subfunctions per se. But because the interaction between the parameters has the nature of a function itself, the function of a microsystem is more than the sum of the functions of the subcomponents (see also [491, 531]).

The principle that functionality can be enormously increased by a greater integration density while system reliability and economy are maintained provides the basis and motivation for future microsystems technology. The integration of electrical and nonelectrical subfunctions on a chip or substrate enhances the performance of microsystems and is therefore particularly interesting. The requirements that must be met when integrating sensor and electronics, as well as the actuator whenever possible, are, however, in part contradictory.

The manufacture of future microsystems will require not only suitable principles but also high-performance materials, technologies, and design systems. New assembly and connection techniques will play a crucial role, as will quality assurance. Present-day solutions, technological approaches, and principles of microelectronics, materials research, integrated optics, process engineering, production engineering, chemistry, biology, and medicine must all be examined with regard to their systems capability and integratability [532].

The development of sensor systems will, however, be influenced by two other trends:

Transition from Batch to Continuous Processes. As production is changed over from batch to continuous processes, information acquisition cycle times become shorter. Direct coupling or integration of self-contained, autonomous sensor-actuator systems (e.g., for metering pumps, variable-speed and variable-torque motors, and so on) will probably be a necessity (see Chapter 6).

Automation. The problems cited in the preceding sections show how important robot-aided sensor systems will be for sampling, sample preparation, disposal of auxiliary substances, and maintenance actions. For example, Figure 180 shows a fully automated pH sensor system with remotely calibrated probe [438]. Figure 181 shows the sequence of automatic functions in a phase model.

Information utilization leads development in a completely different direction.

Figure 180. Example of an automated pH sensor system with remotely calibrated probe [438]

"Model-supported measurement methods," which have now become well established, should be mentioned first [390, 424].

The connection between process model and sensor system implies the ways and means for remedying fundamental shortcomings in measured-value acquisition with the present capabilities of information processing. Given these procedures, unmeasurable process and product properties can be reconstructed from easily measurable quantities through interpretation of a priori knowledge, represented in a mathematical model, about what happens in the process.

Furthermore, experience in petroleum exploration with properly positioned sensors has led to the use of tomographic methods so that, ultimately, spatial representativeness can be achieved on the basis of a one-point (local) measurement.

Modern methods of human – process communication (see Section 11.2) will make it easier to develop temporal single-point measurements by using characteristic curves in product and process configuration spaces (Fig. 182).

Sensor and actuator systems, as the link between material flow, energy flow, and information flow, will be designed in future such that they relieve the load on the central processing units of the process control system or actually become subsystems of it.

Figure 181. Subprocesses in calibration of a pH sensor

Developers and users, particularly in the area of sensor – actuator systems, will need to grow beyond the historic borders of their field and apply a keen and critical sense of analogy to the problem of transferring insights from other experiential worlds into process control engineering.

5.4. The Market for Sensors and Sensor Systems

Extensive market surveys [533, 534], shows and congresses [532, 535, 536] and seminars held by technical societies and manufacturers all come to one conclusion: The already large sensor market (world volume in 1988: ca. € 12×10^9) wil expand even further, reaching ca. € 23×10^9 in 1995 and > € 33 $\times10^9$ by the year 2000 [537]. Figure 183 shows a regional breakdown of the expected boom.

According to the Prognos figures, process engineering and plant construction are the largest customers of sensor and senosr system manufacturers at present (€ 4.6×10^9 in 1988). It will be these users that largely motivate and support the market growth; the absolute increase in sales to these customers will be exceeded only by applications in automaking, the relative increase by applications in building and safety engineering as well as in medical technology (Fig. 184).

If the forecasts are accurate, process engineering and plant construction will account for roughly one-third of sensor sales in 1995 (€ 7.5×10^9). This development will be motivated by requirements for increased product quality and plant availability, and also by more stringent environmental and occupational safety standards.

Figure 182. From process signal to configuration space (process and product property space)

Figure 183. Sensor market broken down by region and year up to 2000 (1 DM ≙ 1.95583 €) [537]

Figure 184. World sensor use broken down by application (1 DM ≙ 1.95583 €) [537]

The Prognos study cited above also shows that plant and process engineering are the dominant users of sensor technology on a region-by-region basis too (Western Europe, United States, Japan) and will probably remain so.

For the sensors used in plant design and construction, Figure 185 presents a summmary of application areas, while Figure 186 gives a similar breakdown for those used by process plant operators. Notable is the dominance of the petrochemical industry, which is accounted for by the high degree of automation in plants now onstream.

Figures 187 and 188 show the sensor market for plant construction and process engineering divided according to the physical quantities

Figure 185. Use of sensor systems in plant design and construction, broken down by industry [537]

Figure 186. Use of sensor systems in process engineering, broken down by industry [537]

Figure 187. Western European sensor market in plant and process engineering, broken down by quantity measured [537]

Figure 188. World sensor market in plant and process engineering, broken down by quantity measured (1 DM $\triangleq$ 1.95583 €) [537]

measured. Clearly the process properties identified as "classical" in Section 5.2 – temperature, pressure, flow rate, and level – account for the highest expenditures, while the properties grouped under "chemical quantities" represent a less important market for the process analysis technology discussed in Section 5.2.

It is interesting to do a cost analysis by the quantities themselves. A comparison of Figures 188 and 189, the latter showing the distribution of process control stations by quantity measured in medium-sized chemical process plants [448], suggests that temperature and level can be measured much more cheaply than pressure and flow rate. This is supported by a market sur-

Figure 189. Number of process monitoring and control stations in chemical process plants, broken down by quantity measured [448]

Figure 190. Numbers and values of transmitters sold in the U.S. market, 1990 [538]

Figure 191. Flow rate and mass flow rate sensors broken down by type (estimated 1988 [537])

Figure 192. Western European sales of flow sensors in 1990, broken down by sensor type [441]

vey [538] that compares the numbers and values of standard sensor transmitters sold in the US market (Fig. 190).

The reason for this disproportion certainly lies in the use of many relatively simple and robust principles for measuring temperature (for example, with the Pt 100 resistance sensor) and level; with regard to the markedly higher figures for pressure and flow, a detailed comparison with other conventional "classical" technology (e.g., orifice plates) makes it clear that manufacture prices here are motivated by market policies. An intimate knowledge of the market reveals that modern "contactless" methods of temperature and flow measurement, which require costly signal processing arrangements, are being offered at dumping prices in comparison with conventional "mechanical" methods.

A more detailed analysis can be done for sensor systems used in flow rate measurement. According to present figures, these represent cost-intensive process control stations (see also Figs. 188, 189, and 190, in which the third to sixth transmitter categories can be employed in flow measurement).

Newer developments in this field make clear the advantages of intelligent field systems with remote diagnostic and maintenance capabilities. The additional functionalities of these systems, which in conventional technology are rather demanding in maintenance terms, should pay off in the long run by lowering maintenance costs and reducing energy losses (e.g., diminished pressure losses). There is an increasingly pronounced trend toward methods such as vortex shedding, magnetic induction, and Coriolis methods (direct determination of mass flow rate)

and away from the older methods of differential pressure and rotameter-type instruments (see Figs. 191 and 192).

Modern trends in flow measurement are reported in [441,539,540].

All forecasts on applications in plant and process engineering agree on the expected development thrusts and market opportunities: biosensors and microsensor technology [531,541].

5.5. Field Installation and Cable Routing

Introduction. Field installation and cable routing denotes the connections and structural work that must be performed to connect the field instrument to the data-processing system in the switch room and thus insure the flow of information between the field level and the process control level.

Modern installation technology is characterized by the use of an individual line from the sensor system to the switch room where the information-processing system (e.g., process control system) is located. Here, "sensor system" means the sensor with sensing element plus the metrology and instrumentation required for data acquisition [383]. It is not important whether the sensor system is made up of one unit (compact device) or several parts (e.g., the sensor plus a 19″ rack-mount transducer in the switch room). In the compact unit, sensing element and transducer are conbined in a single instrument. Compact devices have some major advantages.

As to functionality, there is a clear division between sensor system and data-processing unit. The sensor system generally performs the measurement, while all information processing takes place in the control system or stored-program controllers. The incorporation of microprocessor technology into sensor systems has turned them into "intelligent" systems, even if they show no outward sign of this new capability. The potential of intelligent sensor systems can be realized only through bidirectional communication comprising the transmission of all commands and information. This is also the only way to take advantage of the wide range of possible functional expansions of sensor systems. Field bus technology will not only allow bidirectional communication but also simplify field installation and reduce costs.

The cables needed for field installation are placed along the cable routes provided for them. Cable routing must comply with structural and safety requirements; important points include fire and mechanical protection of the cables. Other practical requirements can be found in the section on cable routing (see page 183).

Field Installation. *Types of Installation.* Even though the prospects for field installations with field bus and field multiplexer continue to be discussed, new systems and components today are generally installed by proven conventional methods. Figure 193 shows five variants of present-day installation practice in Germany [446].

In variants (a), (b), and (c) the transducer is located in the switch room, whereas in (d) and (e) it is in the field. On going from (a) to (e), the amount of functionality incorporated in the field-level device increases:

- Variant (a): The sensor element (e.g., a resistance thermometer) contains no electronics. The transducer is located in the switch room and is connected to the sensor by a two- to four-wire cable. If the cable has three or four conductors, the effect of the line resistance can be compensated. Because there are no electronics in the field and no auxiliary energy is supplied to the sensor, the signals depend only on the sensor and are said to be sensorspecific. The transducer in this variant is normally installed in a 19″ rack.
- Variant (b): The field-level sensor element (e.g., a pressure sensor) has a two-wire power supply cable and uses a second two-wire cable to transmit a signal (0 – 20 mV or 4 – 20 mV) back to the transducer, which is usually located in a 19″ rack. The signals to the transducer are manufacturer-specific, since the sensor signals are altered, but no intelligence resides in the field instrument.
- Variant (c): The sensor element in this variant has electrical preprocessing. In physical terms, the transducer is now present in the field. The manufacturer-specific signal, modulated onto the two-wire cable, is not yet finally processed; for example, linearization and damping have not been performed, and

Figure 193. Development of field installation
PLS = Process control system; SPS = Stored-program controller; PC = Personal computer; U_H = Auxiliary energy; MUS = Transducer power supply; FV = Field distributor

the output has not been converted to a 0 – 20 mA or 4 – 20 mA signal. These functions take place in the 19″ rack-mount transducer, whose power supply also supplies the sensor element through the same two-wire cable.

– Variant (d): The transducer is located at the measurement station and is combined with the sensor element to form an overall system (compact instrument). A 19″ rack-mount transducer power supply powers the compact instrument, furnishing 4 mA. The transducer sends the measurement information to the power supply unit as a 0 – 20 mA or 4 – 20 mA signal, over the same two-wire cable. The transducer generates this information by varying its internal resistance.
– Variant (e): This variant also employs a compact device. Because of the physical principle used, instruments in this variant are supplied with a relatively large amount of auxiliary energy, so that a separate power supply line is necessary. The output signal corresponding to the measured value lies in the range 0 – 20 mA or 4 – 20 mA and can be input directly to post-processing or used for displays in either the switch room or the control room. Hence no other instrument is needed in the switch room.

All these variants have in common that the information-bearing signals from the field instruments are led to a field distributor or distributor box, to which other field-level instruments are also connected. The cable employed for connecting the field instrument to the field distributor is generally a twisted pair or four wires in two twisted pairs, with 0.5 mm^2 shielded conductors. Data lines and cables are described in DIN VDE 0800-0899.

Consider, for example, the 32-pole field distributor. From it, a 32-wire master cable usually runs to the terminal board in the switch room. Partial allocation is also possible, provided this is allowed by the allocation of master cable signal loops to the interface plane and no future change in the signal loops is permitted. The master-cable specifications could be as follows: 32-wire ($16 \times 2 \times 0.5\ mm^2$); i.e., 16 twisted pairs, not shielded pairwise but having a common shield.

In addition to the 19″ interface plane, when required, a connection to a second terminal board is also possible. The second terminal board provides the connection to, for example, the process-level components of the process control system. This connection can be made with a master cable having, for example, the following specifications: 32-wire ($16 \times 2 \times 0.5\ mm^2$); i.e., 16 twisted pairs, not shielded pairwise but having a common shield.

Field Installation in Explosion Hazard Areas. Special regulations apply to the installation and operation of equipment in explosion

hazard areas. These requirements have not been harmonized on a worldwide basis, so that some discrepancies arise. The discussion that follows applies to Europe.

- Definitions and Terms (VDE 0165): The basis for assessing the scope of the requirements to be imposed is a division of explosion hazard areas into zones by the probability of occurrence of hazardous atmospheres. The gases and vapors present in the plant are classified into explosion groups, while the instruments and other devices to be installed are divided into temperature classes. Each temperature class specifies the maximum surface temperature permitted for the device.
  - Zones: Zone 0 includes regions in which a hazardous explosive atmosphere is present at all times or over prolonged periods. Zone 1 includes regions in which hazardous explosive atmosphere is expected to form only rarely and for short periods. Zone 2 includes regions in which hazardous explosive atmospheres are expected to occur occasionally.
  - Explosion Groups: Explosive gases and vapors can be classified into explosion groups according to the minimum ignition temperature of their mixtures with air. The groups are designated IIA, IIB, and IIC; gases and vapors in group IIC are most easily ignited. Instruments and devices must be approved for the appropriate explosion group.
  - Temperature Classes: Instruments and devices for installation in explosion hazard areas are classified into temperature classes corresponding to the maximum surface temperature. The classes range from T1 (max. 450°C) to T6 (max. 85°C).
- Cables: Cables and wiring for circuits that are not intrinsically safe must be selected so that they can withstand the anticipated mechanical, chemical, and thermal stresses. The selection must comply with one of the following standards: DIN VDE 0298 Part 1, 3, or DIN VDE 0891 Part 1, 5, 6.
  On mechanical grounds, wire cross sections should not be smaller than certain values (VDE 0165). Conductors should generally be copper or, under certain conditions, aluminum.
- Placement of Cables and Wires: Cable and wiring penetrations to areas free of explosion hazard must be sealed adequately tightly; possible methods include sand seals, approved elastomers, and mortar seals. Cables and wires should have appropriate protection at points where there are especially severe threats due to thermal, mechanical, or chemical attack. One such form of protection is to place the cables and wires inside pipes. This should be done only with approved piping systems; case connections and transitions to cables and wires must also be approved. Once the installation for the explosion hazard area has been completed, it must be inspected by electrical specialists for compliance with ElexV § 12. A further inspection for compliance with the accident prevention regulations of UVV 4 § 5 must also be performed by an appropriately licensed person.
- Equipotential Bonding: In explosion hazard areas, equipotential bonding is required to prevent static discharges that might cause ignition. A good foundation earth is incorporated when the plant is first constructed, and the structural steel of the building and, for example, the switch room floor structure are grounded to this in star fashion. The interface cabinets and terminal board cabinets, as well as all other units, are grounded to this floor structure, along the shortest path. The interface cabinets contain the transducer power suppiles and other devices. Between two active devices, such as motors, located not more than 2.5 m apart, the measured resistance should not be greater than 0.2 Ω. The measured resistance between an active device and a passive object such as piping, located a maximum of 2.5 m apart, must not exceed 1 Ω.

An electrical specialist must verify compliance with the equipotential bonding requirements (UVV 4 § 5) visually and by measurement. These measurements must be recorded in an inspection record.

Systems with Intrinsically Safe Circuits. In the "intrinsic safety" type of explosion protection, electrical energy and surface temperature are limited such that sparking and thermal effects that could lead to ignition of certain atmospheres cannot occur. In other words, not even

a short circuit can cause sparking. This type of protection exists in all countries that accept the IEC standards, and also in the United States and Canada, which have not yet adopted them.

Only insulated wires (insulation test voltage 500 V a.c.) may be used in intrinsically safe circuits. Several intrinsically safe circuits may be combined in one cable. Cables and wires of intrinsically safe circuits must be labeled or color coded. Sheaths or jackets are color-coded in light blue.

Intrinsically safe circuits and circuits without intrinsic safety must not be laid together in cables, wiring, conduits, or conductor bundles. In cable ducts, insulated spacers must be inserted or wires with certain kinds of sheath or jacket must be selected.

When installing an intrinsically safe circuit with just one apparatus, care should be taken that the maximum permissible inductance and capacitance for the circuit, including cables and wiring, are not exceeded. These permissible values are found on the nameplate of the apparatus. Wires must be treated as lumped capacitances.

Intrinsically safe circuits from the field are generally led to interface planes located in the switch room, which provide the separation from circuits without intrinsic safety. Possible implementations include approved safety barriers and transducer power supplies. The transducer power supply limits the maximum power available on the intrinsically safe side and also supplies a maximum of 4 mA and, say, 15 V to the transducer. The sensor system connected to this device thus has ca. 60 mW available to supply all the electronics.

Comparison of Circuits with and without Intrinsic Safety. The preceding section said that a transducer drawing its power via the 0 – 20 mA or 4 – 20 mA signal has ca. 60 mW at its disposal. This implies that only relatively low-power sensor systems can be supplied in this way; however, such sensors make up well over half of all sensor systems. There are, however, other sensor systems that cannot now be operated at such low power levels. The trend is for marginal systems to be supplied with low power at the expense of reliability, accuracy, and/or stability over time. It should be considered whether these drawbacks outweigh the advantages. Such a decision must be made for each application.

The advantages of intrinsically safe sensor systems and their circuits are easy handling and low cable costs, since only two wires per unit are needed. Intrinsically safe instruments and circuits can also be worked on while in service without having to cut off the power.

When nonintrinsically safe apparatus is used, there must be a separate power supply for the sensor system. That is, separate signal and energy channels must be present (see also Sections 5.1 and 5.2), so that at least four wires are required. If the power supply voltage is, for example, 24 V d.c., the supply and signal lines can be put in one cable. This arrangement has the further advantage that the terminal board plane and interface plane can be omitted.

If the two approaches are compared, the intrinsically safe variant has the clear advantage as to handling, while the other offers significant cost benefits. Futhermore, when using intrinsically safe sensor systems that are barely able to function with the power available, some attention must be paid to reliability, accuracy, and time behavior. *Field Installation in the United States.* Installation techniques in the United States are quite different from those in Europe. In most cases, the cables are placed in conduits.

- Definitions and Terms: Classes are defined as follows: Class I relates to gases and vapors; Class II, to dusts; and Class III, to fibers or fiber dusts. Each class is further subdivided into Division 1 and Division 2. The discussion that follows concerns only Class I areas.
  - Division 1 is characterized by the permanent, occasional, or periodic occurrence of hazardous concentrations under normal conditions.
  - Division 2 is characterized by the fact that hazardous concentrations can occur only under accident or malfunction conditions.
- Cabling in Class I, Division 1: The only types of cabling permitted in these areas are cables in conduits and mineral-powder-insulated cables of type MI with the end closures in stress-relieving grips. Only materials approved for these areas may be used; for example, conduits and fittings must satisfy U.S. codes, some of which differ from the DIN standards. Conduits are inserted directly into the pressure-tight housing. The conduit system is completely "flameproof," so that a

spark originating in the conduit cannot escape to the outside.

– Cabling in Class I, Division 2: Apart from conduits, NEC Article 501-4 also permits sealed track channels or cables or wires of types MI, MC, ALS, CS, TC, or SNM with approved end fittings to be installed in stress-relieving grips.
  Normal wiring is also permitted for circuits that, under normal circumstances, do not liberate enough energy on a wire break, short circuit, or ground fault to ignite an explosive atmosphere.
  Housings, fittings, and connectors generally must not be explosion-protected.
– Installation Practice in the United States: The classification of wiring in the United States is similar to variants (d) + (e) in Figure 195, that is, with a field distributor and master cable to the switch room.

Even when cabling without conduit is permitted, common practice is to place all cables in conduits. This has historical reasons: When installation practice was codified in the United States, intrinsic safety did not yet exist, so all cables were run in conduits; in Division 1, the conduits also had to be pressure-tight. Sensor systems, as well as field distributors, were used in pressure-tight designs (as they still are). This type of installation, designed by piping engineers, was reflected in the standards. Changes, even when they appear to make sense, take place very slowly. By now, intrinsic safety does exist in the United States, but its availability has had little influence on installation practice.

The insurance industry actually promotes the retention of this practice. Plants are usually covered by "electrical insurance," written by companies that approve the installation method and generally expect conduits.

Comparison of European and American Field Installation.

Disadvantages of Conduit Use in the United States: The use of conduits increases the space requirement for the installation, since the routing has to allow for bend radii and offsets.
The cost of installation is much higher, not only because of the placement of the conduits themselves but also because of the difficulty of pulling the cables through the conduits, their inflexibility, and the clumsy and quite heavy pressure-tight distributor boxes.
Additional gas barriers must be placed in the conduits to prevent the movement of gases and vapors and the propagation of flames from one part of the electrical system to another.
In the long term, problems arise from condensation and the pitting that it causes, as well as from the higher transfer resistances due to corrosion. This is important because the conduit system is also used for equipotential bonding. Condensation is controlled by drains through which the liquid can be removed.
Advantages of Conduit Use: The conduits afford mechanical protection to the cables.
As electromagnetic compatibility becomes more and more a factor in plant design, conduits offer much better shielding. Especially for digital data transmission, it is very difficult to separate signals from noise, since they occur in part in the same band of frequencies.

Trends in Field Installation. *Cost Analysis for Present and Future Installations.* An important question in the evaluation of new installation techniques is that of cost. New methods must not only provide technical benefits but should also be, at least, no more expensive. One study has found that future installation practice can make a significant contribution to cost reduction [542].

The comparative cost analysis is based on four cabling concepts in a representative plant.

The plant consisted of 400 process control stations. For the first calculation, these were assumed to consist of 240 analog and 160 binary stations. The second calculation was based on 300 binary and 100 analog stations. For the variants with field bus, it was designated that fewer than half the process control stations could be connected to one field bus.

All design, installation, shop, and material costs were included, from the individual line to the field instrument up to and including the input/output cards of the process-level components.

The results are shown in Figure 194.

Variant I: conventional, parallel cabling. Cost = 100 % (basis for comparison).

Variant II: field multiplexer hardware used at the field level, so that only a few cables (field buses) had to be run from the field to the switch room. The result shows that there are marked

Figure 194. Cost comparison for field installation variants [542]
EV = Final distributor; FM = Field multiplexer; U_H = Auxiliary energy; BM = Bus multiplexer

savings. Cost = 82 % (74 % for the plant with the larger fraction of binary stations).

Variant III: field bus (intrinsically safe; transmission rate 31.25 kbaud) for the field instruments that can be directly connected to a field bus. The remainder of the field instruments are connected to a field multiplexer. Cost = 73 % (77 %).

Variant IV: field buses from variant III compressed into one field bus with higher data rate (not intrinsically safe, 1.5 Mbaud). Cost = 69 % (78 %).

When the analysis of "present-day" instrumentation was extended by distinguishing between separate versions and compact devices, it appeared that future trends in instrumentation would see only the compact instruments still in use, with the intelligent transducer generally forming a single unit with the sensor element. Under severe ambient conditions, it often makes sense to install the transducer with its complement of electronics near the sensor element. Because it is not desirable to connect a 19″ transducer on a field bus, this alternative will largely disappear in future.

Field Installations with a Field Multiplexer. The field multiplexer solution is illustrated in Figure 193, variant (f), and Figure 194. A mixed field installation with field multiplexer and field bus is also possible. The field multiplexer must be approved for service in the explosion hazard area (zone 1). It provides data compression so

Figure 195. Results of the PTB field bus study (category ib, group IIB)

that the total cost of cabling to the switch room, the required terminal board, the 19″ rack for the transducers and their power supplies, and the necessary plant documentation are all substantially reduced in comparison with conventional installation practice.

Such a field multiplexer can be obtained in a range of sizes. The user must decide the number of channels connected to it above which partial or complete redundancy is to be employed. In the case of complete redundancy, a second field multiplexer is connected in parallel. The line from the field bus directly to the input/output cards of the field-level components in the switch room should not be run together with the existing field bus. The I/O interface module can also be designed with redundancy.

One possibility for the individual lines from field devices to the field multiplexer is an unshielded $2\times0.5\,\text{mm}^2$ twisted pair. The type of field bus cable depends on the run length and the data transmission rate. A shielded $2\times0.5\,\text{mm}^2$ twisted pair may be needed for simple applications, a coax cable for more difficult applications. The field multiplexer itself requires external power (e.g., 220 V a.c.).

Field Installation with a Field Bus (see Chapter 8).

– Principles: Figure 195, variant (g), shows a possible field installation with field bus. This is a simple example for the direct connection of intelligent field instruments to the field bus. For use in process situations, especially in explosion hazard areas, the field bus must be of the intrinsic-safety type, so that the disconnection and connection of a bus subscriber is possible even while the system is operating. The bus can accommodate a combination of transducers powered from the bus and transducers with external power, as shown in variants (d) + (e). Important is that the bus interface of the sensor system can always be connected to the Ex“i” (explosion protected, intrinsically safe) bus.

The field bus cabling concepts illustrated in Figures 193 and 194 all relate to a field bus employing copper wire. The field bus can also be realized in the form of an optical fiber cable or a radio link. Radio transmission plays a role in widely dispersed or poorly accessible plants and is not further considered here. Although the “Physical Layer” is now included in the IEC Draft International Standard, optical fiber has not yet been adopted as a physical data transmission medium. Nevertheless, optical fiber technology offers a serious alternative to copper wire.

– Comparison of Copper Wire and Optical Fiber: A field bus installation that seems appropriate for process engineering is that shown in Figure 194. The design in question has parallel individual lines from field instrument to field distributor. The several lines are combined into a two-wire line in the field distributor, and the two-wire line is then led to the process-level components. The field distributor is a purely mechanical component. In contrast, the optical fiber system has as its distributor an active element that forwards the signals after appropriate conditioning.

The advantage of optical fiber technology is that the information is unaffected by electromagnetic interference. The separate power supply to the instruments must, however, satisfy

the requirements of electromagnetic compatibility. For data transmission via copper wires, it can be expected that proper shielding or the use of special cables will still make it possible to comply with electromagnetic compatibility standards such as those of NAMUR. The price of such a cable is, however, much higher than that of a normal bus line.

Very high data rates can be realized with optical waveguide techniques (5 Mbaud). However, such a rate is not generally needed for the connection of sensor and actuator systems through the field bus.

The number of field instruments that can be connected to the international field bus (now in the definition phase) now appears to be 32. For a copper bus line intended for service in the explosion hazard area and also designed to power the instruments connected to it, the number of instruments is smaller, just nine at present. With optical fiber technology, 32 instruments can be connected to a field bus, even in explosion hazard areas. It depends on the application whether it is desirable to connect this many devices to one I/O card in the process-level component for the sake of redundancy. Present-day I/O cards can accomodate eight channels, roughly the same as the number of instruments that can be connected in explosion hazard areas when copper wire is employed.

One advantage of the copper bus line – that the field instruments can also be powered from the bus line – becomes a drawback in many cases. An attempt is sometimes made to use the bus to supply instruments that could yield more accurate, more reliable, and/or quicker results if more power were available. This dilemma of the instrument designer is often resolved with optical fiber technology, since each field instrument then requires a separate power supply.

Consider, for example, a plant with 200 field devices to be connected to the field bus. A calculation gives the following numbers of lines to be run:

Field bus with copper cable:
Number of buses: 23 (9 instruments per field bus)
Number of separate power supply lines: ca. 20 (10 % of 200)
Field bus with optical fiber cable:
Number of buses: 7 (32 instruments per field bus)
Number of separate power supply lines: 200 (possibly implemented with a field distributor)

- Bus Cable: The definition of a single bus cable for all conceivable applications is unlikely, since it would be too expensive for simple applications. The Draft International Standard for the Physical Layer of the international field bus proposal identifies four cable types for the slow (31.25 kbaud) field bus (ISA/SP50-1992-236P):
  - Type A cable: Shielded twisted pair with following specifications:
    $Z_o = 100\ \Omega \pm 20\ \%$
    Maximum damping = 3 dB/km
    Maximum capacitance = 2 nF/km (wire-shield)
    Maximum resistance = 22 Ω/km (per wire)
  - Type B cable: Twisted pair in a master cable with a common shield and certain specifications
  - Type C cable: Twisted pair, possibly in a master cable, but not shielded, with certain specifications
  - Type D cable: Simple (not twisted) pair in a master cable, again with established specifications; the worst of the variants
- Field Installation of Safety Circuits: How safety circuits will be handled in future installation practice can be examined on an application-specific basis. Simple binary operations, such as "if limit switch trips, cut off feed," should be distinguished from more complex conditions for triggering a safety circuit. Such a condition might be a mathematical operation on multiple binary and analog inputs.

The simple binary operation will continue to be wired separately and realized individually by appropriate modules. It may be that an "autonomous" unit in the field multiplexer, powered only by the system, can perform this binary operation, so that the cable need not be run to the switch room. For a more comprehensive safety assessment, it is conceivable that either a hardwired unit or a stored-program controller could be used.

Figure 196. Base concept of the PTB study on field bus use in explosion hazard areas
I_G = base current

Field Bus in Explosion Hazard Areas. The situation is analyzed for copper wire as the data transmission medium. A field bus for service in explosion hazard areas must comply with the explosion protection class "intrinsic safety," so that an instrument can be connected or disconnected while the system is in operation. For low-power sensor systems, such as those usually employed for pressure and temperature, it should be possible to use the bus line for both information and power supply to the instruments.

Even externally powered sensor systems must at least carry out the bus connection in the "intrinsic safety" class, so that these can be connected to the Ex"i" field bus together with instruments not requiring external power.

– PTB Tests: A study by PTB has shown that simple descriptive features make it possible to connect instruments made by different manufacturers to an Ex"i" field bus complying with EN 50020 (Design Standard for Intrinsic Safety) with no special system certification. A variety of cable types were tested for a range of cable lengths and bus supply voltages [446].

Figure 196 illustrates the concept underlying the PTB tests. Only "one active device," the bus power supply, is connected to the field bus. The other devices are "passive" in that they cannot inject power into the bus. In this way, only one device can put power on the line, even in case of a malfunction. The passive devices have low maximum external capacitances and inductances ($C_i < 5$ nF and $L_i < 10$ µH) and minimum input voltages of 9 V. It was further required that each instrument connected must draw a base current of at least 10 mA. The cable length and number of nodes can be optimized by varying the power supply voltage and line length. The concept is applicable to a variety of field buses (Profibus, international field bus, etc.).

The most important finding was that over the wide range of parameters tested, and for various cable types and lengths and various bus power supply voltages, the probability of ignition was not increased by the length of the field bus, the number of bus connections, or the number of instruments connected to the bus. These results are illustrated in Figures 197 (category ib, group IIC, $R'_L = 44\ \Omega$/km) and 5.73 (category ib, group IIB).

For a realistic bus power supply voltage of 15 V, the maximum number of nodes is nine for group IIC and 27 for group IIB. The maximum cable length is 787 m for group IIC, and 310 m for group IIB. The bus power supply voltage or

Figure 197. Results of the PTB field bus study (category ib, group IIC)

conductor cross section can be varied in order to adapt to a wide range of applications.

Important observations from the user's standpoint can be found in [447].

Cable Routing. The sensors, actuators, and so forth contained in a plant are usually connected to the process control system by cables. Cable routes are the "streets" along which the cables are laid.

The project manager, in collaboration with fire services and operators, must identify zones of heightened fire hazard and danger zones as defined in Elex V and VbF at the stage of site and building layout [543]. The overall concept for the main cable and piping routes must be defined at an early point in time and incorporated into the construction plans. Whenever possible, cables should be located only in areas of slight danger. Accessibility and ease of maintenance must always be kept in mind; this includes later expansions. The spread of fire through lining penetrations into fire hazard areas must be restricted by suitable covers.

When cables and pipes are routed together, the possibility of a harmful interaction through thermal, chemical, and mechanical attack must be borne in mind. Cable and pipe routes should therefore be kept separate when possible. When this is not possible and an adequate standoff to hot plant apparatus cannot be maintained, heat shielding must also be provided. Where areas of severe fire hazard cannot be avoided and the functioning of the process control system must be insured under all conditions, a fire-resistant lining or cladding or the flooding or spraying of cable routes may be necessary.

The hanger design must be suitable to the load. Lining may necessitate cooling of the affected section (forced ventilation). Ventilation systems must not extend over the boundaries of fire compartments, so that the spread of fires into other compartments will be hindered. Reliable extraction of cooling air (fumes and smoke in the case of a cable fire) must be insured. Chemical attack must be handled by appropriate selection of construction materials, coating, or jacketing.

The number and location of process control rooms must be selected to yield shorter and more secure cable routes (see Section 10.7). These rooms should be in areas of little danger. Process control rooms and principal cable routes should always be configured so that fires in the rooms and localized fires in plant areas will affect only a portion of the plant (decentralization). The insertion of cables into process control rooms should take place outside the explosion hazard area whenever possible. Massing of cable routes near such insertions should be avoided (subdivision).

If power, control, and data cables are run together, the thermal load on the cable route is diminished; there is no objection to this arrangement provided electromagnetic compatibility is insured. High-voltage cables (>1 kV), however, should be run by themselves. Dedicated cable routes may also be needed for emergency power supply and safety system cables, whose functioning must be guaranteed for as long as possible during upsets.

Bringing cables from outside to inside to supply a floor or platform is generally safer than bringing them from a central cable tray inside the building. When cables are run on exterior

walls or in open recesses indoors, any potential threat from their surroundings should be considered. Working platforms connected by fixed ladders should be built on exterior walls around the height of wall penetrations. In outdoor installations, cables can also be routed on the outside and, if necessary, should be provided with protection against thermal effects.

The cable route must be accessible to firefighters in case of fire. "Cable walls" must permit access to areas located behind them.

Exposed cables must not be run in staircases or on walkways that serve as escape routes.

Placement of cables in underfloor ducts should always be avoided. It creates the danger that aggressive fluids will penetrate the cables or that explosive gas-air mixtures will form and spread without hindrance.

In cases where the use of underfloor ducts cannot be avoided, possible sources of danger should be eliminated by appropriate precautions, for example by sand filling or ventilation. When sand filling is chosen, cables approved for underground placement and having adequate thermal ratings should be selected.

If fire protection considerations mandate the placement of cables in a cable pit or vault, this must be of fire-resistant design. Suitable access must be provided for both fire fighting and the operation of vent and exhaust valves. The chimney effect must be taken into account where cable fires can occur in cable pits. If necessary, the proper design precautions should be taken, such as fire partitions between floors and section-by-section removal of smoke. Compartmentalization should also be considered in horizontal cable routes.

Cable Routing inside Process Control Rooms. The design of cabling and wiring inside process control rooms should allow for some key constraints (see also Section 10.7):

- The penetration to the production facility must be gastight and safe with respect to fire hazards.
- For cables and wires that are to be led into cabinets or cubicles from overhead, or brought from overhead to terminal boards or mounting racks, cable trays should be provided below the ceiling.
- For cables and wires that are to be led into cabinets, cubicles, or racks from beneath, a double floor at least 20 to 30 cm high must be provided (Fig. 357). Cables and wires can be laid free on the floor. For larger cable cross sections, in particular, care must be taken that sufficiently large bending radii are allowed.
- On grounds of electromagnetic interference, cables and wires for power and those for data should be spatially separated.
- Massing of cables and lines should be avoided.
- Design must make adequate allowance for retrofit capabilities.

For high power density, continuous air cooling may be needed. The placement of product and energy piping (except process control system piping) in cable pits is always to be avoided.

In areas where there is a danger of dust explosions, design or organizational practices must insure that accumulations of dust are avoided.

Cable Penetration to the Switch Room. Cables running between the field and the switch room must be led into the switch room through a cable bushing in the wall. On grounds of fire protection, a bushing that meets the required fire protection class, such as F90, is selected. The fire department establishes what fire protection class is required. Not only the cable bushing but also the wall and the door to the switch room must comply with this fire protection class. In a low-cost method of penetration, holes of the desired diameter (e.g., 150 mm) are bored at appropriate points in the wall. The holes are half filled with the cables to be led through them. A fireproofing compound is then injected into the spaces between cables. The remainder of the opening is sealed with adequately close-fitting, flexible plugs inserted from both sides (the plugs should foam up in case of fire).

In future, 3-D CAD tools will be important aids in three-dimensional cable routing and piping design.

6. The Process Control System and Its Elements: Process Actuator Systems

6.1. Principles

Chapters 2 and 5 have pointed out the necessity of adopting suitable structuring practices to

Figure 198. Actuator systems: analogy with the phase model of production

gain an overview of the wide variety of hardware implementations. The need for currency and completeness of description is complicated by the restriction to essentials (for the sake of clarity) and by the fact that technical progress continues after the manuscript of any publication is submitted. For these reasons, an attempt is made here (as in Chap. 5) to achieve some consistency in description, from the information point of view. This can easily be done, in object-oriented terms, by appropriate assignment of attributes. The viewpoint of the modeler is shaped by the objective, as in any modeling process, and if the objective changes then this viewpoint may (or must) change.

Information-oriented process control engineering uses the term "actuator systems" for all technical systems that enable intervention in the process properties, and ultimately the product properties (see Fig. 198). Regardless of the hardware implementation of the system under consideration, this choice of terminology has the advantage that the analysis focuses on the way in which the technical process is influenced or acted on, without necessarily being tied to implementation-dependent nomenclature such as controller, positioner, servo drive, and so forth. Furthermore, the degree of automation, the availability of energy, and the complexity of the actuator system remain initially unaffected by the choice of terms.

If an actuator system is analyzed from this viewpoint, a minimum of three components can always be distinguished (Fig. 199). First there is a functional unit that receives and interprets a control command (actuating command), represented by the control signal (actuating signal) from a higher level. The signal may originate in local components (Chap. 7) of a process control system or in programmable controllers. This functional unit of the actuator system is labeled as "control signal processing" in Figure 199. An energy-furnishing component, controlled by the output signal from control signal processing, can then be identified. In its simplest form, this component (called "servo drive" in Fig. 199) must act as an energy store or else utilize energy supplied via the control signal, passing on this energy in accordance with the control signal. Finally, the third functional unit is the actuator proper, often known as the "final control element." This component is in physical contact with the process properties [544]. The components listed here are found in related forms in the classical control devices (control valve, shutoff valve, ball cock, etc.).

The classical terms control element, control drive, and control signal processing indicate the unambiguously defined direction of action; they do not imply feedback (confirmation of execution or of effect achieved) as to the intervention in the process.

This type of analysis further reveals the problem of separating information flow from energy flow in such simple actuator systems. For example, the energy transmitted by the servo drive to

Figure 199. Structure of a simple actuator system

Figure 200. Structure of an actuator system with auxiliary energy

the final control element can simultaneously be treated as a control signal, but one whose action on the process properties is determined by quantities specific to the system and apparatus. It is clear that the resulting dependence of process interventions on unknown effects, such as turbulence, aging, and the like, does not promote goal-oriented process control.

Figure 200 shows an actuator system in which an auxiliary energy supply has been added. This configuration makes it possible – at least in principle – to separate information flow from energy flow, to decouple the actuator and the drive from the signal processing, and to achieve flexibility in design.

The trend toward "intelligent" actuator systems is illustrated in Figure 201. Here an integrated (dedicated) computer takes care of function monitoring, function maintenance as required, control of the process intervention, and other services relevant to design or maintenance purposes [545]. Communication with the dedicated computer takes place via a display and control panel, a handheld terminal, a PC, or a display and control component [546]. In the long term, communications requirements stemming from additional functionalities will make a field bus solution essential.

The shift of intelligence into the field level permits additional functionalities in the field (local) components. Because the real effect of an actuator operation on the process or product properties is of far greater interest for process control than information such as the actuator position, there is a trend toward coupling of information directly at the local level. The speed control of a pump as a function of the actual flow rate, as determined with an integrated sensor, is an example of fast control loops on the local level.

Figure 201. Structure of an "intelligent" actuator system

In order to survey and classify actuator systems, it is necessary first to define an appropriate viewpoint. In what follows, some criteria are described, leading to the classification presented here.

A breakdown of actuator systems meaningful in the automation context might be based on the degree of automation of process interventions (manual operation, automatic operation), the type of auxiliary energy (electrical, pneumatic, hydraulic, etc.), or even hardware criteria. With regard to information-oriented process control engineering, however, a different type of classification appears more desirable. Actuator systems are analyzed from the standpoint of possible actions on material and energy streams. An attempt to set up such a classification is described here.

The action of an actuator system can be characterized in terms of the possible change in process properties. The manifestation of a property category can be described as changing "continuously" or "discontinuously." The taxonomy that follows therefore uses the criterion of a continuous versus a discontinuous control range.

For example, a mass stream can be controlled in continuous fashion by a control valve or discontinuously by a shutoff valve.

In continuous actuator systems, a further division into proportional and integrating types is possible. Similarly, discontinuous systems can bring about defined absolute changes or incremental changes in the process properties.

An additional feature of actuator systems is important from the standpoint of safety. A system may have an undefined position on failure, where the actuator remains in its most recent position in case of an interruption in the signal or energy flow, or it may have a well-defined safe position (fail-safe). An intermediate group comprises actuator systems in which the drive has a memory characteristic that takes the undefined failure position of the actuator over to a well-defined rest position. For certain processes, this represents an ideal solution from the safety standpoint.

Figure 202 shows a taxonomy of actuator systems based on the criteria discussed above as well as the energy flows to be supplied. Because the application and design features here are generic properties, they apply to all the actuator systems discussed here.

Design features – ranging from physical form, material of construction, and control range to communications, safety, and manufacturer – are listed in a second generic class.

Actuator systems are first classified by objective, that is, actuator systems for material streams are distinguished from those for electrical energy streams.

For each group, systems that effect a quantitative change in the streams are next separated from those that essentially bring about a qualitative change (most often defined in energetic terms). The first type, acting quantitatively on the streams, are described as "controlling" sys-

Figure 202. Taxonomy of actuator systems for material and energy streams

Figure 203. Taxonomy of actuator systems for material streams

tems in Figures 202, 203, 204, while the second type is described as "transforming" systems.

If we consider first actuator systems for material streams (Fig. 203), the group of controlling systems include "distribution" systems such as screw conveyors, metering apparatus, etc., and "throttling" systems such as control valves, shutoff valves and gates, cocks, and so forth. In manufacturing and process engineering these two classes are often regarded as independent groups.

The category of transforming systems includes not only the turbine and the burner, but also the pump. This is admissible since the primary use of a pump is to increase the pressure of a material stream; thus the pump, as an actuator system, alters a qualitative property of the material stream.

Other examples of material transforming systems can easily be classified; for example, a stirrer plus drive in a stirred tank reactor, or of a roller, a press, or a tubular reactor.

Figure 204. Taxonomy of actuator systems for electrical energy streams

Figure 204, based on the same classification principle, shows a taxonomy for actuator systems working on electrical energy streams. The quantity controlling systems include relays, thyristors, transistors, and gate-turnoff (GTO) devices (see also Section 6.3); the energy transforming systems include generators, lighting, motors, heating, etc.

A more detailed breakdown of energy controlling systems can be found in Section 6.2, which also distinguishes between switch and positioner on the basis of whether the control range is continuous or discontinuous.

Development trends in actuator systems can be briefly described as follows:

- Development from the actuator to the actuator system with integrated intelligence and the incorporation of lower-level control functions
- Expanded communications capability with field multiplexer or field bus [547]
- Improved service life, especially for actuators, due to novel materials, designs [548], and automatic maintenance techniques [549]
- Increased use of electronic frequency converters for motor speed control[550]

The trend toward intelligent actuator systems is possible because of advances in microelectronics. For example, a valve position controller with an integrated 16-bit microprocessor is now available [551]. Self-parametrization makes it much easier to adapt the device to the drive and the valve; the internal control loops of the actuator are more powerful; and the adaptability to a range of service conditions has led to a reduction in the number of position controller types needed.

The augmented functionality of actuator systems cannot be fully utilized unless there is a suitable facility for communication with higher levels in the process control system. Parametrization, function monitoring, and maintenance require special information, which will be made available by future field bus and communications concepts (see also [552] and Chap. 8).

Section 6.3 deals with the trend toward variable-speed drives. It is seen that improved control behavior (linear control characteristic), reduced energy consumption (especially under part-load conditions), motor power and motor losses restricted to the design values, and optimal matching to the process machinery used offer substantial potential for economic and technical optimization.

6.2. Actuator Systems for Material and Energy Streams

Introduction. Together with sensor systems, actuator systems link material, energy, and information streams in processing and manufacturing systems. The control path with sensor system, controller, and actuator system forms a closed control loop. Changes, whether in perturbing values, setpoints, controlled variables, or other quantities, manifest themselves in the system and also in the signals transmitted to and by these devices. With the aid of actuator systems, the material or energy stream is set in the con-

trol loop as a function of the system deviation. The action also depends on the characteristics of the control path, the sensor system, and the controller with its control parameters influencing its dynamics. With regard to the dynamics, the control element can be included in the control pathway and the servo drive (actuator drive) can be included in the control device. In the open loop case, the intervention in the process is effected through a control command, which takes the form of a control action or a manual action. The control pathway need not carry feedback.

In actuator systems, the control command (the output of the controller) must be tranformed to a control signal (Fig. 199). Servo drives in the form of power amplifiers are needed for this purpose. These may be pneumatic, electric, or hydraulic, but hydraulic drives are rarely used in process engineering. Because of their well-known advantages in manufacturing and robotics, however, hydraulic power amplifiers are preferred in these fields. They are robust drives whose high power density results in good control of complex motions, accurate positioning under load, and wide speed ranges. Problems, however, such as poor damping, marked nonlinearity, and load-dependent eigenfrequencies, should be mentioned.

Continuous and switching control elements are distinguished, just as control elements with memory must be distinguished from those with a well-defined rest position. Single action modes or combinations may be required, depending on process or safety requirements (see also Fig. 202).

Continuous control elements effect a steady or gradual change in mass or energy flow within the design range, while switching elements act in a step-by-step manner. In process control engineering, there is often only a minor difference between the two types. Control elements of continuous or switching type can be designed by modification of globe and plug valves, cocks, shutoff valves, and the like. The required characteristic determines whether the required accuracy of positioning or control can be achieved under given pressure conditions. The characteristic associated with the system (inherent characteristic) can be matched to the operating characteristic. With regard to accuracy of positioning, a corresponding resolution of the control signal must be ensured. Control elements such as slide valves or solenoid-actuated valves have a design that makes them unsuitable for continuous control and positioning.

Control elements with electric motor drives have memory and remain in the last position adopted if the auxiliary energy goes off or the control signal fails. Ordinarily, control elements take up a well-defined position on a failure of auxiliary energy or control signals. For material streams, this is generally full open or full closed, and for energy streams, full on or full off. In safety devices, this position is called the "safety position." Control elements such as gate valves or stop cocks with double-acting pneumatic drives can be made to exhibit memory by the addition of blocking valves; the use of return springs or pneumatic buffers can result in their exhibiting a well-defined rest position. The size of the pneumatic buffer depends on the number of switching operations and the quality of sealing. The advantage over energy storage in springs is that several switching operations can be performed after the occurrence of a fault.

The term "control" is explained in DIN 19 222 [553]. Control is the changing of mass, energy, or information flows by means of control elements. Standardized definitions of the terms actuator, actuator system, control element, controller, and control machine have not yet been adopted. They are used at present even though the demarcations between them are often not clearly defined.

Examples of Actuator Systems; Delimitation. Controllers or final control elements are also referred to as actuators or actuator systems, in analogy to sensors or sensor systems. Ordinarily, "sensor" means an element that performs a detection or measurement function. If this element is equipped with signal processing and other modules that permit further options, the result is a "sensor system." The analogy to "actuator" and "actuator system" can be made complete only if the "actuator" is defined exclusively as the part that comes in contact with the product.

Accordingly, the actuator is the final control element or control machine itself, that is, the throttling organ, the pump, the compressor, the blower, the resistance coil (for heating), or the fluorescent tube or incandescent lamp (for lighting). The corresponding actuator drives would

Figure 205. Structure of an actuator system

Figure 206. Actuator system for mass streams: structure of a control valve

Figure 207. Actuator system for mass streams: structure of a variable-speed pump drive

be (for controllers of material streams) the diaphragm drive, the piston drive, the rotary drive, the motor, the motor with converter when speed control is required, or the switch or power controller for heating for lighting. The last two items apply to the case of controllers for energy streams. In common usage, however, the terms actuator, actuator system, controller, and final control element are often employed as synonyms, generally for the complete device.

Generally, the actuator system (Fig. 199) consists of a final control element (control machine), a servo drive, and a control device. Figure 205 shows the setup. The final control element is moved by the servo drive in order to change the flow of material and energy. The servo drive is driven externally with the control signal from a control device. With further devices, parametrization, configuration, status, feedback, and other signals can also be transmitted.

If these terms are applied to two well-known cases – the control valve and the variable-speed pump drive – the consistent representations in Figures 206 and 207 are obtained. Figure 206 shows a controller made up of a control element in the form of a valve (fitting) with a throttling organ, a pneumatic drive, and a control device. The control device is a positioner, which processes the control signal (as setpoint) to the position of the drive (as actual value) in the course of a closed-loop control operation. Along with the control section, the positioner includes a power section, where the control signal is amplified and which is to provide the desired positioning of the

Figure 208. Actuator system for energy streams: structure of a switch for control or safety purposes

Figure 209. Actuator system for mass flow: structure of a positioner for a heating system

control element with the required quality and dynamics. The terms control element, actuator, and fitting are often used synonymously.

The variable-speed pump drive is a typical interconnection of a control element in the form of a pump, a control drive in the form of a motor with power section integrated into the frequency converter, and a control device in the form of an information-processing component. The control signal is fed to the control device, which monitors, reports, limits, diagnoses, tests, generates error messages, archives, establishes a connection as needed, communicates, and so forth; it can also be parametrized and configured (see also Fig. 201). Section 6.3 goes into more detail on variable-speed drives with d.c. and a.c. motors.

The simplest case of control of an energy stream is the making and breaking of a circuit to a consumer. Figure 208, which is based on Figure 205 and analogous to Figures 206 and 207, shows an actuator system whose control device receives the sensor system signals of interest to the operator, and appropriately switches auxiliary energy to the control drive (coil) in order to activate the control element (switch).

The terms can also be extended to a positioner in a heating system (Fig. 209). This is a continuously adjustable heating device, whereby the control signal is generally a unified current signal (0/4 – 20 mA). The control device, with monitoring, testing, reporting, communications, and display functions among others, drives the control drive or power section. The energy stream to the control element or to the heater coil is adjustable from the control room or locally. It can be set automatically or by hand – depending on what devices are connected in circuit with it – anywhere in a design range specified by the designer.

Points to consider in the design of a controller for a material stream include dynamics, operating point, positioning forces, operating range, characteristic, safety position, operability, service under explosion hazard conditions, and sealing. Design steps include the determination of the nominal diameter (DN), the rated pressure (PN), the construction materials for components in contact with the product, the type of sealing, the positioning forces, the noise emission, the possibility of cavitation, and the matching of the inherent characteristic to the operating and control drive characteristic. In the case of the variable-speed pump drive or a control machine, special consideration should be given to the motor startup characteristics, the by-

Figure 210. Descriptive structure of a control valve for design and installation

pass circuit, the power rating of the motor and the converter, the motor heating, the torque ratios, the proper matching of the actuator (in the form of a pump) to the motor, the cooling of the converter, the use of tested and certified devices for service in Zone 1, and so forth. In this connection, a number of regulations, specifications, technical guidelines, and so on must be complied with. A process control station data sheet is filled out in which the product, device, process, and design data are entered along with data on safety, availability, quality assurance, etc.

With the station data sheet and the requirements from the piping and instrumentation diagrams or the bid specifications, the appropriate design is prepared and the process control system station plan is generated. The procedure is illustrated for a control valve (Fig. 210); see also the generic classes in Figure 202.

The control valve consists of the valve itself plus a lever or plunger drive, depending on the motion of the throttling organ. The valve can be realized in the form of various devices, such as a globe, peristaltic, or plug valve. The design specification differs from one type of throttling organ to another. The configuration or the way the devices are installed in a process plant can also vary. The best installation position depends on the product, the heating medium, the sealing system, the flange design, and so forth. The design of the lever drive can be based on equipment offered by several manufacturers. As a rule, however, only a single design specification is considered. The same holds for the case of a plunger drive. The devices with their designs, the layouts, the selection, the installation of these devices have been fully described elsewhere. There are also many DIN, IEC, and VDMA standards. In many cases, calculation and design programs are offered with the respective data sheets. Examples of commercially available programs can be found in [553].

The path of the control signal via the control signal processing section of the control device, the control drive, and the final control element itself, where it is transformed to a position value, is shown in the middle part of Fig. 201. The control element alters a process value in a process element. Generally, one measured quantity is provided to the control device from the process. This quantity is needed as a control or monitoring quantity for the controller or actuator system. Feedback to the process control system or to local components takes the form of messages. In the control device, the actuator computer, together with its communications devices, is shown in Figure 201. This device performs function monitoring in the form of self-tests or externally initiated diagnostic tests. The result of these tests is directly displayed locally in error messages, error displays, status messages, and so forth, or (in future technology) will be transmitted over a field bus to a remote location. An integrated display/control panel is always included in complex actuator systems for local parametrization and configuration. Human – machine communication takes place via this interface.

Taxonomies of Actuator Systems for Material and Energy Streams (see Figs. 202, 203, 204). In what follows, an attempt is made to devise taxonomies of various actuator systems under various criteria [554]. The entity – relationship model is employed, converted directly to file structures (see Chap. 2 and [555]).

Controllers (actuator systems) are first classified in terms of their tasks. Controllers for material streams and those for energy streams are grouped separately (Fig. 211). At the next level

Figure 211. Taxonomy of actuator systems for mass and energy streams

Figure 212. Taxonomy of actuator systems for mass streams according to functional criteria

of detail, controllers for energy streams are broken down into switches (e.g., Fig. 201) and positioners (Fig. 202).

Figure 212 shows the classification by technical and functional criteria. Each actuator system consists of a control element, a drive, a control device, and energy storage, if required.

The control element (actuator) may consist, for example, of a valve with a throttling organ, a pump with case and impeller, the inductive coils of an induction furnace, a halogen lamp, the mechanical contacts of a power contactor, or the power thyristors or transistors of a positioner. The drives (power section) are listed in a similar way. In more complex actuator systems, the control element and drive are based on a control device (information-processing component). This component, in the form of an information or signal-processing section, processes, conditions, and transmits the signals to the actuator system and also from the actuator system to and from higher-level devices.

Figure 213. Taxonomy of final control elements for mass streams

When safety and availability requirements are more stringent, energy storage is required. If the auxiliary energy fails, this stored energy brings the control element to a desired safe position via the drive. Examples are compression and tension springs, which release energy on demand and test the "emergency case" upon every switching operation. A pneumatic buffer can be used as energy store; from which energy stored in compressed air can be withdrawn for a certain time and with which repeated switching operations can be carried out. In other applications, batteries and backup power supplies maintain safe operation. Battery-backed systems can be kept operable without interruption; with emergency generators, on the other hand, interruptions must be reckoned with from the outset. It is often sufficient that the motors continue to run after a short interruption.

Final control elements for material streams are classified as shown in Figure 213.

The control element may be a control valve, whereby the function of the throttling organ is carried out by translational or rotational motion. The throttle bodies are said to be straight-line (translational) or rotational.

Another possible classification, in accordance with the terms of DIN IEC 534, Part 1, is illustrated in Figure 214.

Mention should be made of the many and varied process connections, sealing systems, fitting types, throttling organ configurations, noise suppression options, drive design possibilities, and control device types.

The control element can also be a controller without auxiliary energy but employing spring or weight loading to insure the admission of a certain quantity (setpoint value) of material per unit time. Large numbers of such devices are used not only in process engineering, but also in heating and air conditioning as well as other branches of industry.

Control machines are becoming increasingly important with the development of modern power electronics, because they can be operated much more efficiently in variable speed mode than controllers with throttling organs. In systems with throttling devices, energy must first be introduced into the material stream, and then part of the energy dissipated by throttling [556]. Cavitation can result, with outgassing, phase-change effects, and noise as the consequences. For this reason, variable-speed motors are increasingly used to drive control machines (see Section 6.3 and [557]).

Drives. Each actuator system has a power section or drive system (Fig. 215), which must be matched to the control element or actuator. In devices with throttling organs, translational and rotational control drives are distinguished. Motors can be classified into d.c., multiphase (Fig. 216), compressed-air, and other types.

Figure 214. Taxonomy of a control valve [DIN IEC, Part 1]

Figure 215. Descriptive structure of an actuator or power section

Depending on the network form, power, required dynamics and quality of control, field and later maintenance conditions, and so forth, the designer selects an asynchronous, a.c., synchronous, or d.c. motor. Attributes of these objects include power, rated voltage, speed, number of pole pairs, motor and explosion protection, case shape and size, type of protective enclosure, weight, ventilation, position of terminal box, manufacturer, supplier, model number, and stock number.

Devices for controlling energy streams can be broken down into switching devices and devices continuously controlling the energy stream (Fig. 211). Typical representatives of switching devices or switches are relays, contactors, disconnectors, power circuit breakers, and current-limiting circuit breakers. Each of these consists of a drive (operating mechanism) and a mechanical system, which in the simplest case (e.g., in a low-voltage, high-breaking-capacity breaker) is operated by hand. More complex devices employ a magnet coil or, in the medium- or high-voltage range, a motor drive. Switching functional elements are normally-open, normally-closed, and changeover switches. Figure 217 illustrates this taxonomy, but only for the mechanical switch side; electronically operated devices with corresponding functions can be classified similarly.

In the continuously operating devices, the energy stream or power can be set within a certain range, so that matching to a certain operating point within a stated range is possible (see also

Figure 216. Taxonomy of servo drives for the example "motor"

Figure 217. Taxonomy of discontinuous actuator systems for energy streams

the schematic diagram in Fig. 209). Positioners or position controllers can be used to set the voltage, current, frequency, and other values [556, 558]. Rectifier technology includes devices to transform or control electrical energy by the use of rectifier valves. The fraction of electrical energy switched, controlled, and transformed in the power electronics will increase steadily with growing requirements on the controllability and transformation of electrical energy. Applications for power electronics include industrial drives, electric heating, and energy generation and distribution. The basic functions of positioners can be classified as shown in Figure 218 (see also Section 6.3).

The basic functions are rectification, inversion, a.c. conversion, and d.c. conversion. In rectifiers and inverters, which are not regarded as actuator systems, the direction of energy flow is specified. In a.c. converters and d.c. converters, the direction of energy flow can generally be reversed. Variable rectifiers make it possible to control the output voltage and frequency and thus the energy flow. A possible classification of

rectifiers by direction of energy flow, into unidirectional and bidireactional rectifiers, would also be conceivable where the energy flow can be reversed. The a.c. and d.c. controls shown in Figure 218 should be emphasized; these can be used to control heating and lighting and also in power systems. Further, the various link converters used for motor speed control should be mentioned. There are various pulse-amplitude-modulated frequency converters, pulse-width-modulated frequency converters, and link converters. These devices are commonly referred to as motor controls, heater controls, and lighting controls (see Figs. 212 and 219). Their attributes as individual objects are power, voltage, current, driving signal, manufacturer, accessories, limiting, torque limiting, type of starting torque enhancement, power and torque transducers, and braking unit.

Figure 218. Taxonomy of continuous actuator systems for energy streams

In general, without going into the individual technical differences between frequency converters, a classification such as that shown in Figure 220 can be employed. As shown above, the devices can be broken down into final control element, control device, and power section (control drive). The entire equipment is also called a control machine in accordance with IEC 514. All centrifugal, turbine, gear, and plunger pumps, as well as special-purpose pumps, are included in the category of machines for handling gases, liquefied gases, and liquids. The control drive consists of a power section and the motor. The power section and the control device are commonly integrated, except for the transformer of the rectifier.

Control Device. The control device has two functions: to match the actuator system to various equipment connected before it and to the mode of operation, and to match it to the final control element and the drive itself. Figure 221 shows a possible classification.

In more complex actuator systems, control devices are made up of devices such as controllers and monitors with their respective memories, actuator buses, display/communications/feedback devices, accessories, integrated display and control panels, and so on. It can be expected that the control device will go through major changes in the future. The control device should make possible matching to the connector in conventional or smart technology (see Section 5.3 and Chap. 8) or in bidirectional field bus technology. The type of central electronic controls common up to now, with expensive cabling between the sensor and actuator systems and extensive setup operations during commissioning, will be modified for the sake of more easily understood, less expensive, distributed signal processing. For the user, such a device will become a "plug-and-play" unit in spite of its complexity. Not yet fully achieved are networking capabilities and a consistent, manufacturer-neutral, menu-based operator interface as desired by both operator and designer. Futhermore, major efforts are needed in order to bring about a unified field-level communications technology based on internationally accepted standards. Such technology will permit interchangeability of hardware across manufacturers. These interfaces must satisfy increasingly stringent requirements, partly because of the trend to "rationalization" and the desire for a central service. In the near future, this area will become a focus of the activities of manufacturers, users, and developers (see also Section 5.3 and Chap. 8).

The control section, as a module of the control device described above is needed for the human – device interface (Fig. 222). In the simplest case, the actuator system can be set with a handwheel, or via a manual control signal from the supervisory device of the controller or from the process control system. In automatic mode, positioning takes place after signal processing

Figure 219. Device object tree for process control systems at the field level

Figure 220. Descriptive structure of an actuating machine

Figure 221. Structure of a controlling element

Figure 222. Structure of a human – device interface

with specified setpoint values; this function is performed automatically.

Figure 222 illustrates the possibilities of manual and automatic operation. Thus, there are two interfaces: a human – device in manual mode, and machine – device in automatic mode.

In manual operation, interventions can be accomplished by

- A local control station, in the simplest case a handwheel, lever, or the like
- A display and control panel, integrated into the actuator system, on which the system can be set
- A control panel at the supervisory device, for manual and automatic operation
- A screen mask on the display and control component where manual control signals can be set or nominal values and tolerances can be specified

In automatic mode, interventions take place

- Between the final control element and the field controller
- Between the control element and the individual controller in the control room
- Between the control element and the controller component in the process control system, stored-program controller, or PC

Outlook. The object-oriented representation in data processing has the following advantages for the user: Objects are presented in an intuitive, structured, transparent form, and searches (e.g., for a certain device) are carried out in prompted mode.

Because devices in this representation are merely sketched, further detailing is necessary at the lower levels if installation, shop, and maintenance workers are to find individual repair or replacement parts with given specifications and given relationships to other devices. Similar requirements arise in the design of a process monitoring and control system, where the specification document dictates the selection of devices; their identification by, say, a CAE plot symbol in a process monitoring and control functional chart; or their representation in a positional world with lower- and higher-level devices.

On the basis of Figure 219, this point is illustrated for the example of a device object tree [559].

In the object-oriented representation, the devices required for a process control system are described by groups. For example, they can be broken down into structural elements of equal rank: sensor system, actuator system, auxiliary device, information-processing components, electrical, control air system, infrastructure, and installation materials. Sensor systems are classified by physical quantities; actuator systems, by the criteria discussed above; auxiliary equipment, into input and output devices, switches, and protective device; information-processing components, into controllers, supervisory devices, software modules, stored-program controllers, and process control systems with their components, such as central unit, local components, display and control components, and so forth. Note that a "pure" or textbook-type classification is not possible in many cases, and for practical reasons a compromise must be found, especially in the case of actuator systems. Here, continuous control devices are listed under the structural element "actuator system," except for solenoid valves and switching-type control valves, while switching devices for energy streams are classified exclusively as "auxiliary equipment." Naturally, a practical worker seeking a controller without auxiliary energy will look among the other controllers under "information-processing components," and if in need of a reducing station will look under "control air system." Under this object-oriented approach, once a certain device has been found, design specifications, device configuration and installation standards, and even manufacturing standards (if needed) can be found in a further level having the same structure and the same nomenclature of structural elements. After a device has been selected, designed, and configured, the respective activities can be carried out in CAE applications modules, such as process control station data sheet, process control station plan, procurement, and so forth.

Such a system has the further advantages that innovations in hardware and installation can be adopted better and more quickly and that workers in these fields obtain design and manufacturing standards in easily understood form. What is more, changes in standards and directives can be complied with in a better and more economical way (see Chap. 9).

Finally, two more developments should be mentioned:

- Workers in automation, information, and microsystems engineering are energetically pursuing:
  - Piezoelectric actuators [560]
  - Shape-memory actuators
  - Magnetoelastic actuators
  - Micromechanical actuators
  - Actuators using electrorheologic and magnetorheologic liquids
  - Precision positioning with electromagnetic actuators

Information on these developments can be found in [561].

- The trend in the chemical industry toward smaller-sized batch processes is generating a demand for much faster metering systems, which can only be realized by direct coupling between metering element and flowmeter (see Chap. 5) [562].
- In addition to a number of other advantages (energy savings, decrease shear gradient at almost closed position of the control valve – important for biotechnological and polymeric materials – smooth start-up, etc. [563]), by means of r.p.m controlled drives, pumps with variable performance can adopt the functions of classical control valves [564, 565].
- The coupling of sensor and actuator systems in self-sufficient control loops at the field level allows the amount of communication with and the computing load on the process control system to be decreased. Expecially in the area of building automation, interesting application are already available at reasonable cost.
- In the field of sensor/actuator systems in particular it will be necessary for developers and users to move away from the traditionally narrow viewpoint and, by means of analogy, apply insights from other areas to process control engineering [564].

6.3. Electrical Drives in the Chemical Industry

Development of Electric Drives. Electric drives have long been used in large quantities in various applications in industry. The majority of the drives are not speed controlled in any way. The first major application for variable speed drives was in traction, applications, especially in locomotives and trams, and later also in metallurgy. Variable speed drives subsequently found their way into a large number of applications in general industry. The general trend is from fixed-speed to variable-speed drives. Typical applications for modern variable speed drives are, for example, in the field of traction, the main drives for TGV and ICE trains, main propulsion drives for ships, and a large number of process-oriented applications in the pulp and paper, chemical, and metallurgical industries. Other typical application areas cover manufacturing industry, energy production, and water treatment.

Most motors in use today are not speed controlled. About 95 % of all motors sold today are asynchronous motors, of which 95 % run at fixed speed, connected directly to the mains. In future, the number of asynchronous motors driven by frequency converters is expected to grow rapidly, at ca. 15 %/a, while the growth rate for all variable speed drives is ca. 7 %/a.

Figure 223. World market for variable-speed a.c. drives in 1991

The estimated world market for variable speed drives was ca. $ 3.3×10^9 in 1991, of which 55 % is a.c. and 45 % d.c., a trend that will intensify in the future. The a.c. market (Fig. 223) is concentrated to Europe, the United States, and Japan. The rest of the world accounts for ca. 10 % of the total market. The market split into the

various power ranges reflects the differing structures of the industry and the price of energy in the different areas. In terms of numbers, the majority of drives (ca. 90 %) are small (<5 kVA), ca. 8 % are in the range of 5 – 50 kVA, and only 2 % exceed 50 kVA. The number of motors controlled by variable speed drives in Europe is about 5 % for 5 kVA, 9 % in the range 5 – 50 kVA, and 16 % for >50 kVA. The larger the motor is, the more likely it will be driven by a frequency converter. Process demands at higher powers often require variable speed drives, and the realized energy savings are economically more important.

Figure 224. Areas of use of variable-speed drives in the German chemical industry

The basis for this development is the a.c. motor, which has a simple, robust, cost-effective, reliable, and rugged design that is relatively easy to modify for use in Ex-areas. Developments in power and control electronics have made drives more technically advanced and cost effective. The price of an a.c. drive has decreased by about 10 %/a during the last ten years, while the price for d.c. drives has shown a decrease of ca. 4 %/a. The total cost of a drive (drive electronics and motor) is about equal for a.c. and d.c. although a.c. can be slightly more expensive in the middle power ranges. The total life cycle costs for an a.c. drive are in general lower than those of a d.c. drive.

The German chemical industry has a large number of motors in use (Fig. 224), one estimate [561] is ca. 500 000 units. The average power is 7 – 13 kW, the minimum power is 120 W, and the maximum power is 6800 kW. About 80 % of all drives are smaller than 10 kW. Only about 10 % of all motors have variable speed; in two-thirds of the cases, this is achieved by pole changing. The large proportion of fixed speed motors indicates that other control methods than variable speed are used, usually control valves, bypass control, or mechanical variators.

Most of the drives in the chemical industry are used in the main process, although many drives are used in auxiliary processes in energy production and raw and wastewater treatment. The use of variable speed drives has increased markedly during the last few years. Most of the applications are pumps and fans, but several other applications are also quite common [566].

Variable speed drives are used mainly to improve process control [566]. By controlling the speed of the prime mover, the material flow can be better controlled; variable-speed pumps can handle logistics and the dosing of materials with low losses and low machine strain, thus improving process control and reducing mechanical wear. Variable speed drives are also used to replace control valves in polymer and biotechnical processes. The soft start feature of variable speed drives eliminates pressure shocks in pipes when motors are started and they also significantly reduce the thermal and mechanical strain on the motors at start, which usually permits more economic dimensioning of the total system. The supply dimensioning is eased by the lack of high starting currents and compensating capacitors. The direct drive energy savings, especially in centrifugal machines, are also of importance when deciding the type of drive required. A 40 % saving for variable-speed a.c. drives compared to fixed speed solutions is not uncommon. Variable speed drives also make less noise, as machines are used at optimum speed, rather than at full speed at all times.

Table 11. Main electrical data of various power semiconductors

	Thyristor	GTO	Bipolar transistor	IGBT	FET	MCT	FETh
Voltage, V	6 000	4 500	1 600	1 600	1 000	3 500	4 500

Development of A.C. Drive Technology. *Power Semiconductors.* The development of power semiconductors is summarized in Table 11. The first commercially successful power semiconductor was the thyristor, developed in the early 1960s. The thyristor is a four-layer device that can be turned on (changed into a conducting state from a nonconducting one) by the application of a gate pulse. Because it works by positive feedback, to turn it off, the current through it must be decreased to zero, after which it regains its blocking, nonconducting state. If the applied voltage across the thyristor does not naturally reverse sign (as happens for components connected to the mains supply), a commutation (turn-off) circuit is required. This increases the size and the complexity of a thyristor drive and also limits the maximum switching frequency achievable. Thyristor PWM drives normally switch at ca. 400 – 600 Hz and the motor is thus fairly loud with a motor loadability of ca. 85 % at 50 Hz. The dU/dt is ca. 500 V/s. Thyristors are now used only in high power drives.

The next major power semiconductor is the GTO (gate turn-off thyristor). As the name implies, it is a thyristor that can be turned off as well as on. This is achieved by careful design of the semiconductor layers and device geometry. As the device can be turned off, no additional commutation circuitry is needed and the size of the drive thus decreases. The GTO is fairly sensitive to a correct handling at turn-off and is today used in high-power drives (200 kW) and at high voltages (>1 kV). An advantage of GTOs is that they are latching devices, like thyristors, and thus require no control power when they are in a stable state (on or off). In the case of short-circuits in the output, they pose problems, as they do not inherently limit the current and are difficult to turn off in this state. The switching frequency and dU/dt are comparable to thyristors.

In lower power drives today, the main power component used is the bipolar transistor. With this component powers of up to 200 kW can be achieved, and up to 600 kW with several transistors in parallel. The device consists of two Darlington-connected transistors. By controlling its base drive the device can be made to turn on and off. Transistors require a continuous base drive in order to conduct, i.e., they do not latch. In the case of shorts they are more forgiving than GTOs but they require a stiff base drive to turn them off. The simpler turn-off requirements simplify the control circuitry and allows drives to be smaller and more efficient. With Darlingtons, switching frequencies of up to 4 kHz are achieved with a dU/dt of ca. 1 – 2 kV/s. The higher switching frequency increases the motor loadability to ca. 90 % at 50 Hz and reduces motor noise.

In newer ranges of frequency converters, the power semiconductors are IGBTs (insulated gate base transistors). These devices are a combination of voltage-controlled field effect transistors (FETs) and bipolar transistors, connected so that the control is like the voltage control of a FET and the power side is of the low-drop bipolar type. These components inherently limit the current and they are thus more forgiving and easier to handle in short-circuit situations than transistors. As they are voltage controlled, not current controlled like bipolar Darlingtons, the control circuit is simplified and reduced in volume. There is also a significant reduction in the rating of the auxiliary power supply, as IGBTs require less control power than transistors. The IGBT allows switching frequencies of up to 20 kHz which increases the motor loadability to 100 % at 50 Hz and gives an attainable dU/dt of 5 kV/s.

New components are being developed by power semiconductor manufacturers, for example, MCTs (MOS controlled thyristor) and FETh

(field effect controlled thyristor), hybrids between conventional thyristors and FETs, with voltage-controlled switching and a very low state loss, which will reduce the size of future drives.

Frequency Converters. Frequency converters are divided into two main types, depending on their construction. One is the current source inverter (CSI) and the other the voltage source (PWM). Current source inverters contain a controlled thyristor bridge connected to the supply and a second one connected to the motor. The two bridges are connected by a large inductance. The current to the motor is controlled by the input bridge, and the frequency is controlled by the output bridge. The motor voltage then adjusts itself to the actual current and frequency. In older types, the output bridge consists of thyristors, which means that the motor is a part of the commutating (turn-off) circuit of the thyristors and thus every inverter and motor forms a pair. In newer drives the thyristors are replaced by GTOs or bipolar transistors, which eliminates this coupling. Due to the basic construction with a controlled input bridge, CSIs are suitable for single, stand-alone four-quadrant operation. As they contain a large choke, however, they are usually bulky and the drive may be noisy.

The most common type of drive today is the voltage source inverter. It consists of a diode input rectifier, which generates a constant intermediate circuit voltage. This intermediate circuit consists of a choke and a large capacitor. At lower powers the choke is often omitted. This causes the harmonic content of the supply current in the main to increase, so for installations requiring smooth mains current drives with an intermediate circuit, chokes are recommended.

The rectified and smoothed voltage is supplied to the motor via an output stage, which controls the voltage and the frequency of the waveform applied to the motor. The most commonly used components in this stage today are bipolar transistors at lower powers and GTOs at higher powers. The bipolar transistors are being replaced by IGBTs. The waveform applied to the motor consists of a pulse-train with a sine-weighted duty cycle (pulse-width modulated, PWM). The inductance of the motor filters the current resulting from this pulse-train to near-sinusoidal shape. The effective voltage applied is normally increased in direct proportion to the output frequency to generate a constant flux in the motor. This is possible until the mains voltage is reached (i.e., up to 50 Hz) and with the latest modulation techniques up to about 60 Hz. At higher frequencies the voltage remains constant, and the flux diminishes in inversely proportion to the output frequency. The maximum speeds that can be reached with standard squirrel cage motors are of the order of 40 – 120 Hz; higher speeds require special motors. The normal PWM inverter described above is used in about 90 % of all cases. It is a simple, straight-forward approach to variable speed control, requiring no special motors or any sort of feedback. As it is an open loop drive, its dynamics and precision are not of the highest degree. It is, however, sufficient for pumps, fans, extruders, conveyors, and simple machines.

For higher performance, vector-controlled drives are used. In these drives, a feedback signal is required from the rotor position. This information enables the controller to precisely calculate the torque on the motor shaft and also indicates the exact position of the shaft. The information is then fed to a PWM output stage, which controls the current and frequency in the desired manner. With this drive, full load torque at zero speeds and precise position control can be achieved. The drive always requires an encoder on the motor. Typical applications are synchronized lines, paper-machine drives, rolling-mill drives, and all applications where the torque must be precisely controlled.

Power semiconductor development has had a major impact on the size of drives. The average volume per power has decreased to 1/6 in ten years. Today the decisive factor determining the size of a drive is its thermal design. Modern power semiconductors allow a junction temperature of up to 150 °C, corresponding to a case temperature of ca. 100 °C. The case temperature is limited to about 80 °C, sometimes up to 100 °C.

Modern control electronics use 16 bitprocessors with designs for 32 bit processors or for signal processors in development. This trend of incorporating more computational power in the drive will continue, so that the possibilities for control offered by modern drives will increase. The requisite discrete logic is commonly realized in an ASIC (application specific IC). These are monolithic ICs built us-

ing standardized logic cells, so that a defined, application-specific function can be realized. One ASIC can replace several hundred conventional TTL circuits with large savings in space and powering. Lately, technologies have become available that allow a similar approach to analog circuit design.

These developments have also increased the reliability of drives. The MTBF (mean time between failure) for drives in 1983 was ca. 40 000 h, while in 1993 it was ca. 250 000 h. The number of parts necessary to build an 11 kW frequency converter has decreased from 2500 to 500, a trend that will surely continue. The basis for this lies in modern component technology, both for logic components and for power components, and in the better possibilities for simulating and measuring complicated and fast processes.

For critical applications, redundant drives are still recommended, especially in cases where there is a risk of injury to humans, where the process flow is critical and must be controlled at all times.

An aid to achieving high process reliability is the use of switchgear converters, which allow easy changing of drives and of system configuration. Combined with a fully digital commissioning and down-loading of various drive parameters, this allows an extremely rapid change of drives, simply by changing a cassette.

An external sign of quality control and an internal tool is a certification according to ISO 9000, Parts 1 – 3. This standard defines the requirements regarding standardized working methods and documentation for a company or profit center. Quality is also achieved by standardization of methods in development, production, and testing. Standardization allows a high repetition rate when using various components, either software or hardware. This allows a short development time for new products without endangering product quality.

As an example of standardization, consider solving EMC problems (electromagnetic compatibility), that is the problems occurring when devices have to work in an electrically noisy environment. The main standards in use are the various DIN/VDE and CISPR standards. Generally speaking, two types of interference occur:

- Low frequency: frequencies up to ca. 5 kHz and earth currents
- High frequency: frequencies from ca. 50 kHz to 30 MHz

Low-frequency interference can be divided into periodic interference (caused by nonlinear components such as diodes and thyristors) and aperiodic interference (caused by supply disturbances). High-frequency disturbance is caused by switching phenomena in power switches. The various interferences can influence other devices nearby, either through radiation or conductance. Generally, conducted interference is more problematical.

A standard solution to high- and low-frequency interference is adding filters to the input of the device. At high powers this is usually difficult, bulky, and expensive, especially as the high- and low-frequency ranges require different features. It is also possible to separate the power supply to interfering devices from all other supplies, or to use a d.c. distribution system, in which 12-pulse circuits for supplying the d.c. power distribution minimizes the 5th and 7th harmonic current in the supply. This d.c. power is then supplied to independent output stages in order to drive motors.

Aperiodic disturbances include supply failures, which can last from milliseconds to several seconds. Drives usually use the kinetic energy in the driven load as a supply when the supply fails and then accelerate to the set speed when the supply returns. The possible time the drive can survive depends on the type of load and its kinetic energy. Usually there are also other questions of synchronism: can the drives run when the total process is otherwise down?

To eliminate undesirable influences from the power stage on the control electronics, fiber optics are used. This allows a clean separation of the control circuits, which can be standardized irrespective of rated power, and the power stage, which can be separately optimized and standardized. This technique also allows customized interfaces to be developed for standardized, mass-produced drives.

In future, it will be possible to eliminate a significant number of sources of high- and low-frequency interference by using so-called resonance circuits. For example, with single-phase inputs, a completely sinusoidal supply current can be achieved. A further development allows

switching of the power semiconductors in a zero-power state, which reduces disturbances.

Drives as System Elements. A drive is regarded as an actuator from the systems engineering standpoint. It is connected directly to the process and to a field bus. Normally, only commands and status information are exchanged through the bus system, but in special cases the entire commissioning and the parameter setting must be performed associated through it. This can be done either from a remote panel connected to the field bus or from the engineering workstation functioning as bus master. The goal is to move the detailed process control to the sensors and actuators exchanging information through the field bus. To reach this goal intensive work is being done to standardize the field-bus protocols.

Figure 225. Information structure of a modern drive

A modern a.c. drive (Fig. 225) is functionally divided into the actual motor control and the interface with the external world, with control and setting possibilities. This concept uses at least two microprocessors (one for each function). The drive is self-contained, and no external power is necessary. It is in many cases possible to process data locally to control the drive. Such a drive will form a yield unit (Fig. 226), decreasing the load on the process controllers and on the control system. This is especially important in fast processes (for example, in dosing applications), so that the central control is not burdened with all details of the process. The drive is then closely connected to the process through local measurement and feedback, making it possible to implement local control of, for example, volume and heat flow. The bus system transmits only commands and status information from the various field units; details are handled locally.

Figure 226. Field unit

The planning of a drive system is identical to the general planning of control systems. The basis for the planning is a requirement specification drawn up by the user, describing the function of the drive and its behavior in special cases such as mains failures. This must be carefully thought through and defined, as experience shows that most of the subsequent problems can be avoided here. Based on the requirement, an engineering specification is written, describing with which devices and with which technologies the desired functions will be realized. Here, the economic restrictions of the various projects must be taken into account. This work is usually facilitated by standardization within a plant or company. It is also recommended that a test specification be written for the possible delivery tests, preferably in cooperation with the chosen supplier.

When dimensioning and specifying a drive, the following features must be taken into account: voltage, power, torque requirement as a function of speed, speed range, control signals, braking capability, cabling recommendations, and EMC aspects. The behavior in special cases (short circuits, overloads, underloads, earth faults, etc.) must also be considered. The desired motor features must also be defined (construction, EX class, loadability, etc.).

Drives are considered actuators in modern CAE systems and they are treated as standardized objects with certain, defined features [567].

When a drive has been specified and built, an acceptance or delivery test is often required,

especially in the case of high-power drives. The goal of a delivery test is to establish that the drive fulfils all the requirements defined in the requirement specification. It is important to specify in detail how the various features must be measured to ensure that the specifications are fulfilled. At lower powers, a type test certificate is usually sufficient. The supplier must be able to test the behavior of the drive at high break-away torques or at mains failures. A test proves that the drive works as specified and allows a first, coarse setting of parameters to be done. It is usually not possible to optimize the drive; this must be done under true working conditions on site.

This optimization is made easier by digital technology, which also allows data transfer and trouble shooting over telephone lines. A multichannel recorder integrated into the drive also facilitates trouble shooting. For trend analysis, the drive itself stores and displays certain key data as a function of time. This can be done by a process control system, but it is simpler if the drive makes it itself and transmits only the results to the control system. The analysis of the trends makes it easier to judge when maintenance is needed, and avoids being bound to a fixed time interval. One example of this is the calculation of when bearings need to be lubricated. In this case, the drive calculates the lubrication interval and indicates when it is necessary to lubricate the bearings. This time depends on the speed at which the motor is running and can be appreciably longer than the time calculated from the nominal speed of the motor.

Trends. Two directions can be distinguished in the development of drives. On the one hand motors, and on the other hand power electronics and information processing electronics are continually being developed. In addition, a development in the mechanical construction of electric drives can be traced.

New motor ranges better suited to the use of converters are being developed. Standard motors are designed for mains use, as 95 % of motors are connected directly to the mains. Use with a converter makes different demands on the motor. FEM methods help when new, converter optimized designs are being simulated and built. They also aid in developing new high-speed motor concepts by optimizing the rotor slots for inverter use. The new slot shape reduces the losses for a 100 kW motor from 4 kW to 0.8 kW. This motor is designed for a compressor drive with a speed of 10 000 rpm.

The main problems of high-speed drives are mechanical and concern bearings, lubrication, and life time. Conventional lubrication is sufficient up to about 16 000 rpm above which it is necessary to use oil fog lubrication, which increases cost.

The high speeds also allow better material utilization. The high speed motor allows a higher power for the same motor size, or a smaller motor at the same power rating. In high-speed applications, gears are completely eliminated leading to lower investments, less maintenance, and better total efficiency.

The development of new magnets makes it possible to manufacture motors with permanent magnet rotos. The materials development has been rapid, making it possible to obtain realistic performance at a reasonable cost. The cost for neodynium magnets is today about 300 $/kg, allowing the development and sale of special motors. These motors have high efficiency, a power factor equal to unity, and a simple positioning drive without feedback can be realized, as the motor has no slip. Powers up to 100 kW have been reached under laboratory conditions. Research in this sector is concentrated on production methods, as it is difficult to work permanent magnets.

A motor of this type is also well suited to integral motor applications. In these motors, the motor and the drive are mechanically and thermally integrated, making it possible to talk about integrated field units consisting of motor, power electronics, and information processing electronics.

In the inverter, several areas are being developed. The development of microprocessors for the consumption and automotive industries makes powerful and cost efficient microprocessors available for use in drives as well. Semiconductor manufacturing technology also allows the design and manufacture of large ASIC circuits to replace discrete logic. The high processing power available makes it possible to realize complex algorithms, for example, the so-called flux control of a.c. motors. The magnetic vectors in the motor are calculated based on the position of the switches in the output power stage and on measurements of the currents and voltages.

Figure 227. d.c. distribution

This requires a very powerful processor if it is to be performed in real time. This control method gives a standard a.c. motor dynamics superior to those of a d.c. motor.

The powerful processors make it possible to use adaptive control in motor control as well as in a possible controller built into a field unit. It is possible to optimize the motor control as a function of load. These adaptive methods make commissioning easier and are also a step in making drives more user-friendly.

Other trends are control algorithms that take into account the mechanical features of the shaft between motor and the driven machine. With an elastic or possibly an electroviscous clutch between motor and machine it is possible to reduce the impact of torque shocks in the load on the motor, but control of the load is more difficult. An algorithm of this type allows the use of smaller motors. Applications can be found in rolling mills and in long and heavy conveyor drives.

To reduce the size of the inverter and to modularize it, several approaches are being pursued. One is the so-called matrix inverter [569], which connects a three-phase motor directly to a three-phase supply and allows the motor speed to be controlled. The motor voltage does not correspond to the full mains voltage and thus a special motor is needed. One difficulty with this concept is that switches able to conduct and block in both directions are needed, and such components are not yet available in monolithic form. Semiconductor manufacturers are developing these components. As the matrix inverter does not contain any bulky components, intermediate circuit chokes, or and capacitors, it is a good candidate for integrated solutions.

Another solution for standardizing drives is d.c. distribution (Fig. 227) [568]. Instead of having one rectifier bridge, choke, and capacitor bank in each drive, the separate drives are supplied with a d.c. voltage from a common source. This larger unit contains one rectifier, choke, and capacitor bank. It can be smaller than the combined power of the individual units, as it is often possible to use the regenerative power from braking drives to supply driving ones. Typically, considerable savings are achieved, for example, in centrifuge applications, where by braking one centrifuge the energy can be used to accelerate others. The mains rectifier must only supply the energy lost. At higher powers it is also possible to use multiple-pulse connections to reduce the strain on the supply. Galvanic, periodic, and aperiodic disturbances are also easier to control.

A further step in modularization is the combination of power switches and their controlling circuits in one package. Modules are today available containing power switches and their drivers and protection circuits [569]. Such modules reduce the size of the inverter and its reliability increases as the number of separate components decreases.

This trend towards higher integration has also reached the chip level. Chips will soon be available with several functions integrated. This is called SMART power. Further in the future lies chips integrating power switches and total control of the drive. There are no theoretical difficulties in integrating the matrix inverter onto one chip but many practical difficulties. The limits of what can be done today lie at one power switch and its immediate drivers and protection circuits at a voltage of 600 V. These chips are very expensive, as volumes are small, the production process complex, and yields low.

The developments in the fields of power electronics, information electronics, silicon technology, and mechanics will combine in the form of integrated devices, where most of the necessary functions are integrated. The devices will integrate all necessary sensors, actuators, controls, and protections in a single mechanical unit.

The energy savings made possible by using variable speed drives, not only in the drive itself but through the total energy supply chain can be quite substantial. When a control valve is replaced by a variable speed drive, the efficiency of the total system is significantly increased, especially at low volume flows. The total efficiency can increase from 11.5 % to 23 %, an increase of 100 %. These savings reduce environmental pollution and require smaller investments, as the available energy is used more efficiently.

6.4. Electric Power Supply Systems

Principles. A useful way to visualize the structure of electric power supply systems in industrial plants is provided by the level model (Fig. 228, see next page). This scheme assigns a central role to the process power supply system, which connects actuators and sensors on the "consumer" level with power plants via medium-voltage distribution units on the "transport" level.

The process power supply system is tailored to the needs of each plant and must satisfy requirements under the following three headings [570]:

- Adequate capacity under normal conditions. The specific requirements are as follows:
  - Design for operation under rated conditions
  - Availability of electric power at any desired location
  - Flexible delivery of electric power under various service conditions
  - Voltages suitable for various consumer interfaces
- Availability requirements fall into three groups, each with its own set of objectives:
  - Availability from the safety standpoint (occupational safety and health, environmental protection)
  - Availability from the process engineering standpoint (product quality, safety of equipment)
  - Availability from the logistics standpoint (capacity of vendors, production costs)

  In engineering terms, this means:
  - Limited effects on the process when power disruptions occur
  - No interference of one electrical consumer with another
  - Limited effects on the power supply system in case of operation upsets (e.g., fires).
- Safety of electrical equipment. The specific requirements are as follows:
  - No danger to personnel
  - No environmental hazards

These three sets of requirements completely describe the profile of requirements for the process power supply system.

This section describes the essential concepts employed to meet the stated requirements [570, 571]. By way of illustration, the process power supply system for a wastewater treatment plant is described in [572].

Implementation of Normal Power Supply. The basis for supplying electric power for the nominal operation of a plant is established in the design phase. Here, the three-phase switchgear and control gear is dimensioned in view of the predicted requirements of consumers; utilization and demand coefficients are employed for this purpose. The numbers and sizes of power transformers needed are also determined at this point. Direct-current power supply systems are designed by a similar method, with the closed-circuit current and estimated component peak loads as starting points.

Under normal operating conditions, the entire power supply system of a plant is secured by splitting up the power demand among a number of sources, using in-plant generating capacity and imported power.

The relationship between in-plant and imported power depends on a number of factors, including the size of the plant and seasonal variations in steam demand.

In the chemical industry, the principle of cogeneration (combined heat and power generation) is used in creating the optimal power generation system.

Figure 228. Level model of power supply

The fact that power to run the plant comes from two sources does not affect the design of electrical equipment inside the plant. The production process is embedded in a complex, two-dimensional network of cables that covers the entire battery area, connects supply to consumpxtion, protects the process systems, and insures any redundancy that may be required.

Cable networks in industrial plants may be radial or meshed. The radial design is more important today. The meshed network, which offers the advantage of two-way supply, is declining in importance, in part because problems can arise in dealing with the short-circuit power when existing facilities are expanded.

For special cases, distributed generation with diesel-generator sets or battery-backed converters serves to deliver reliable power. This approach should be used only when the solution for the normal case is not technically feasible or when the economics are very unfavorable.

Direct current systems are generally designed in distributed form within the plant unit or section. In future, the increasing number of variable-speed drives may also lead to other structures, such as d.c. networks.

Cable and installation costs can be controlled if the location of switch rooms and battery rooms in the central plant buildings is tailored to the process and/or such facilities are distributed in accordance with demand concentration.

Modern switchgear technology can react quickly to service changes by virtue of

- Modular switchgear design
- Busbar distributors, which are especially suitable for laboratories and workshops
- Worksite distribution boards for installation jobs

Process power supply systems in normal service are designed for standard voltages. Commonly used voltages are as follows:

Data acquisition and processing	24 V d.c.
Lighting	230/400 V a.c.
Wall receptacles	230/400 V a.c.
Low-voltage, low-power motors	230/400 V a.c.

Low-voltage motors, general	500/690 V a.c.
High-voltage motors	5 kV, 6 kV, or 10 kV a.c.

Special situations may require special voltages, such as 25 kV or 30 kV for electrolysis processes.

Implementation of High Availability (Conceptual Solution). Before the adoption of measures to enhance process power supply systems, two points must be considered:

- The availability of power supply systems in general is normally higher than 99 %. Outage time per year, as a rule, is in the range of minutes. This holds for every point in the network and for each consumer.
- The cost of upgrading, with the aim of approaching even closer to 100 % availability, increases with rising power level, increasing number of hierarchical levels in the system, and decreasing outage length. It is not, however, possible to achieve 100 % availability.

The profile of requirements for the process power supply system, as set forth in the bidding specifications, is met by standard and special practices.

Standard practices include the following:

- Use of network architecture typical of industrial plants, with multiple pathways at the supply and generation levels and complex network structure at the transport and distribution level (Fig. 228)
- Use of the IT network
- Use of modular switchgear
- Installation of A – B machinery, with one machine always on stream and the other on standby

Special practices include:

- Inclusion of a standby power supply system
- Upgrading of d.c. power supply system to a protected d.c. power supply system
- Splitting up both switchgear and cable installations into two subsystems
- Compliance with interference immunity requirements

In that follows, practices of a special nature are discussed in more depth; among this group of practices, only those involved in standby power supply and protected d.c. power supply are covered.

Two types of standby power are important for process power supply systems in industrial plants (Fig. 229):

- Standby power from a second, independent network
- Standby power from a standby generating system (diversity of power sources)

Figure 229. Standby power supply system

Standby power supply from a second, independent network is implemented by means of a reserve, backup, standby, or emergency ring feeder (Fig. 228), continuously supplied via automatic voltage detectors.

In general, when standby power supply systems are employed, the bidding specifications must list consumers by permissible outage time and assign them to classes of low-voltage switchgear. Figure 230 shows a classifiction that has proved acceptable as a first rough scheme.

Figures 231 and 232 identify types of low-voltage switchgear and the classes to which they are assigned.

Class 1 consumers must be further broken down for in-depth analysis.

Protected d.c. power supply systems (Fig. 233) feature 100 % reserve capacity because of

- The dual feeder arrangement
- Additional backup of each feeder in case of line outage

Classes of low-voltage switchgear	Possible outage times to consumers on failure of normal power supply	Details of low-voltage switchgear	
		Number of feeders	Devices actuated on failure of normal power supply
Class 1	0–15 s	2	Backup system continuously on line and ready
Class 2	>15 s		Backup system automatically switched on line
Class 3	At least until restoration of normal power	1	

Figure 230. Classes of low-voltage switchgear, possible outage times, and details of implementation

This redundancy must be extended to the data transmission and processing system, that is, to the cards in the subracks if possible.

Implementation of Safety. The terms safety, protection, and danger are interlinked by the concept of risk. Safety practices are intended to insure that the limiting risk is not exceeded. Such practices are mandated by legislation, regulation, engineering codes, and plant-specific direc-tives issued by operators.

Figure 231. Classes and variants of low-voltage switchgear

In the case of power supply equipment or power supply systems in general, "safety" refers to two independent objectives:

- Protection against electric shock (personnel protection).
- Protection against failure of the electric power supply system, which is ultimately a question of "reliability" (safety of equipment, protection of product and plant). This

Figure 232. Classes and design variants of low-voltage switchgear in plant with A and B machines

Figure 233. Protected d.c. power supply system

kind of protection is achieved by means of the measures employed for high availability.

Apart from functionality, protection against electric shock has been the second dominant theme in power supplies since the start of electrical engineering [573]. Notable among the many standards now in existence is the extensive VDE code, which is continually updated.

The practices listed below serve as examples of how personnel protection is achieved in process power supply systems for the chemical industry:

- Increased use of 30 mA ground-fault circuit interrupters. This switch cuts off the flow of fault currents that could cause fibrillation.
- Installation of devices safe against touch by the hand.
- Application of the accident prevention specification VBG 4, "Electrical Installations and Equipment."
- Wider use of safety switches on drives.
- Application of power supply options originally intended for escape route lighting to overall production power supply systems (Fig. 234) [574].

Environmental considerations apply chiefly to process engineering. In general, these requirements do no impact on the process power supply system, which comes into the picture only when "reliable" power is required for devices affording protection or limiting damage to process control systems [575]. It must be verified whether a standby power supply system or a proteted d.c. system is adequate. One type of such a "secure" power supply system is a high-availability power supply system.

Figure 234. Lighting system fed from the specially protected network

High-Availability Process Power Supply System for a Wastewater Treatment Plant (Example). If a plant unit does not have its own waste disposal facilities, a central plant with biological treatment stages is of fundamental importance for maintaining production in a chemical plant. Such a treatment plant requires a high-availability power supply system, which must comprise all the levels of the power supply scheme and extend all the way down to the process control components in the field as well as control rooms [572].

The quantity structure of the plant as built is as follows:

- Distributed process control with dual host computer system
- 1800 process control stations
- 530 uncontrolled 3-phase drives with total power consumption of 10 MW
- 70 controlled electrical drives with total power consumption of 3.5 MW

Figure 235. Voltage levels in a chemical plant

The following voltages are available (Fig. 235):

High voltage: 220 and 110 kV
Medium voltage: 25, 10, and 5 kV
Low voltage: 500 V for motors;
380/220 V for lighting, wall receptacles, computers, and hand tools; 24 V for measurement and control apparatus

Comparison with the level model (Fig. 228) shows the relationships to be as follows: The high-voltage network corresponds to the import and generation level; the medium-voltage network, to the transport level; the low-voltage network, to the distribution level.

The dual-bus structure illustrated in Figure 235, with the consumers separated into two subsystems, insures that the failure of one unit (e.g., a transformer or feeder) affects only some of the consumers at levels lower in the hierarchy. The failure of both system would, however, lead to shutdown of all consumers. However, this must be avoided for particularly important consumers. In such cases, further standby power supply practices come into play:

- Use of diesel generators
- Use of battery-backed uninterruptible power supplies
- Use of protected d.c. power supplies

Figures 236, 237, 238 show these backup arrangements for the low-voltage (500, 220, and 24 V) systems in the wastewater treatment plant.

Figure 236. 500 V low-voltage supply system in a wastewater treatment plant

7. The Process Control System and Its Elements: Distributed Control Systems

7.1. Principles

The task of the process instrumentation and control hardware is to assist plant management in the control of its plants and in the control and monitoring of its production processes [576].

This chapter discusses the structure and function of process instrumentation and control hardware. The structure is discussed on the basis of a reference model.

In a general sense, process instrumentation and control hardware comprise all devices between the sensors and actuators and the operator controlling the process (see Fig. 239 and 363).

The process instrumentation and control hardware must perform a number of distinct functions. Figure 240, for example, shows a metering device. The required functions can be classified as follows:

- Controlling the process
  Automation functions that permit the self-contained control of plant units and process steps. Example:

Figure 237. 230 V low-voltage supply system in a wastewater treatment plant

Figure 238. 24 V low-voltage supply system in a wastewater treatment plant

Figure 239. Process monitoring and control system

If action "metering on," then meter from B 1 to B 2 x liters at q L/s.

– Enhancing the safety and reliability of the process
  Functions prior in time, independent of control function specifications, that intervene in the process in order to enhance its safety and reliability. Because of high required availabilities and special performance provisions, these functions are often implemented in a separate "protective level." Example:
  If L 2 > L 2 max, pump K 1 is disabled.
– Providing displays
  Display functions that report plant and process status to the operator in a concentrated and easily understood form. Example:
  Display level L 1.
– Generating messages
  Message and alarm functions that explicitly notify the operator of certain events and provide information to the central message and alarm processing system. Example:

If L 2 exceeds L 2 max, transmit a message. (Class: "Alarm"; text: "L 2 max alarm")
- Archiving
  Archiving functions to store records of events and status logs. Examples:
  Archive all reports.
  Archive level L 1 every 10 s.
- Generating and interpreting reports Recording and evaluating (interpreting) functions that retrieve, evaluate, and print out archival and current data when a certain condition or command occurs. Example:
  Log the last metering operation performed (starting time, ending time, quantity, events).

Figure 240. Example: metering system

If all functions to be performed by the instrumentation and control hardware are arranged in accord with the functionally abstract "level" model of the process control functions (see Section 2.2 and Fig. 17), some basic conclusions can be drawn as to the automation of this system.

The lower levels of the hierarchy contain many parallel functions with high intervention frequencies. These functions are chiefly suitable for automatic processing by process control devices. At higher levels, the intervention frequency generally decreases, but certain functions (e.g., load recipes) require the transfer of large amounts of data.

The automation of these functions generally proceeds from bottom to top, in keeping with the hierarchical breakdown of process control functions.

Different plant sections can differ in degree of automation. The degree of automation can be divided into four levels [577] (Table 14). Each degree includes not only the automation of the respective process control functions but also the automation of the associated safety/reliability functions. A safety- or reliability-enhancing function is assigned to the level at which it intervenes in the instruction branch. A safety function "if pump temperature > permissible maximum → turn pump off" is assigned to the individual function level; a safety function "if coolant temperature > permissible maximum → turn column off" is assigned to the plant section level.

The functions that a specific process instrumentation and control system must perform can be set down in a requirements list.

In principle, a project specification consists of a list of such required individual functions. Some of these functions, as shown in Figure 241 [578], are carried out by the plant operator, the rest by the process control system. The term "automatic" refers to a function that is performed by the process control system without external action. The degree of automation is the fraction of all functions that can be represented by automatic functions. Nevertheless, the overall scope of the control task must be considered regardless of the degree of automation. Each function that does not take place automatically must be performed by the plant operator. By changing the operating mode, the instantaneous degree of automation can be made lower than the maximum degree of plant automation provided for in the design (see Fig. 242).

Figure 241. Degree of automation

When examining the properties of a process monitoring and control system, a distinction must be made between the external functional viewpoint and the internal structural viewpoint. The external functional view regards the finally configured process instrumentation and control system as a "black box" having certain functional qualities. The internal structural viewpoint regards how the system is structured and how the individual functions are implemented.

Figure 242. Auto/manual selection

From the process control standpoint, the internal structure of the process instrumentation and control hardware is often of secondary interest. The required automation functions, safety and reliability functions, archiving functions, operator and monitoring interfaces, and so forth can be implemented under a wide variety of system concepts. The differences, however, manifest themselves in important supplemental properties. The plant operator, for example, might see differences in system reaction times, the way in which data surges are controlled, the failure characteristics of components, or the central coordination of workstations. Important from the plant management viewpoint, then, are additional properties that cannot be implemented simply as individual functions but result from the structure of the process instrumentation and control system as a whole. The same applies even more so to the planning and operation of a monitoring and control system. Such additional properties of importance include the following:

- Transparency of structure
- Ease of operation
- Structure with few defects
- Capability of modular expansion
- High availability of individual functions

These can be realized only if they are incorporated in the control system design, i.e., in the internal structure, right from the start.

Historical Development. Today, the phrase "modern" process control systems refers more precisely to distributed or decentralized systems. The world of process control engineering before the development of the type of system discussed here (i.e., before ca. 1975) featured two extreme structures, both of which still exist.

In the *totally parallel structure*, each control task (control action, display, recording, etc.) is performed by a discrete device or combination of discrete devices. An example is the compact controller used in the implementation of a control loop. The parallel system terminates in the control room with a great number of instruments, buttons, and lights. It is left to the designer to ensure that the operator can scan the panels without becoming overstressed in critical situations (see Section 8.2).

The decentralized structure means that a plant so equipped has a fairly high availability, since the failure of a discrete device generally affects only the control task directly assigned to it. The solution of complex control problems, however, requires considerable interlinking of the individual process control stations (see Fig. 65). With discrete devices, this networking can be implemented only through explicit interconnection of devices. Subsequent changes of task are therefore expensive because the system must be rewired, and the flexibility of such a plant is low.

For more complex applications, there was the *totally centralized structure* implemented by the process control computer. This structure, which features the maximum degree of centralization on a single device, has all the process monitoring and control functions concentrated in one device, which is intended to alleviate the disadvantages of discrete-device technology.

All control tasks are carried out by a central computer with interfaces to the process. Individual process control stations are linked together by software, so that the scheme can easily be modified, for example, if the recipe is changed.

The resulting flexibility is partly offset by the lower availability of the plant. A failure of the central computer affects the entire process. Therefore, this structure has generally been used only in conjunction with special practices such as hardware redundancy or subordinate backup systems, which have lead to higher costs for such plants. Nevertheless, the centralized structure in this form still plays a role in the landscape of system structures [579].

Modern decentralized process control systems now fall between these two extreme structures (Fig. 243). The search for an optimal structure has led the manufacturers of these systems to solutions that differ in the degree of decentralization.

Figure 243. Decentralized process monitoring and control system compared with central process control computer and discrete-device structures

In simplified terms, a decentralized process control system arises through the logical subdivision of a centralized system. This approach is useful because only the use of a process control computer provides the conditions for implementing process monitoring and control functions through digital computer technology.

The development of microprocessors has made the desired or necessary computing power economically viable. Thus, another important prerequisite for the creation of decentralized process monitoring and control systems was fulfilled [580]. Such a system consists of individual computer components, each of which exhibits the properties of a process control computer to a limited extent. These components are linked together by a communication system. As a whole, they have the same capacity as a large central process control computer. However, the decentralized structure leads to higher availability than a centralized design.

The development of process instrumentation and control systems has followed three distinct lines:

- Decentralized stored-program controller systems
- Integrated decentralized process monitoring and control systems
- Intelligent central systems with dumb peripherals

Most process monitoring and control systems can be placed fairly unambiguously in one of these classes. Differences in historical development of the three groups have led to variations in characteristic features such as size of decentralized components, structure of system communication, type of internal processing, integration of operator control and monitoring into the overall concept, and type of design.

The Decentralized Stored-Program Controller (SPC) System. The starting point for SPC systems was the individual SPC (or programmable controller), which is a self-contained unit performing a particular automation task. The emphasis was on the solution of binary networking and sequencing problems. SPCs were conceived as an alternative to relay controllers, which were becoming increasingly complex, costly, and inflexible (as to wiring). For this purpose, the SPCs were for optimized fast execution of binary logic functions, the integration of control and monitoring functions initially playing a very minor role. Elements such as buttons, switches, displays, and lights were employed to operate the SPC and observe its functions. These were connected to the SPC via conventional field-level inputs and outputs. Outwardly, the SPC thus behaved as a wired discrete control device.

The development of SPC systems has led to three major new capabilities:

- Binary-word processing for handling integer and real variables
- Connection to serial bus systems for data exchange with other SPC components

– Support of display-aided operator control and monitoring systems

Compatibility requirements have dictated consistency of internal structure in the development of SPC-aided systems. Present-day process monitoring and control systems based on SPCs thus show traces of their original functions.

SPCs have gained wide acceptance. Other apparatus frequently contains self-sufficient automation components based on them and is sold in pre-assembled package form. Software creation and design are performed by the apparatus manufacturer, so that special in-house control system know-how can be exploited and protected.

From the plant engineering standpoint, manufacturing automation has been and still is the domain of SPCs. An early development was the linking of SPCs and bus systems to form large networks. The purpose of these communications systems was to permit the sharing of data, especially control data and status messages, between SPCs and between the central control computers and the SPCs. A typical feature is simple variable sharing, in which the communication event and all shared variables must be individually designed. An adequate integrated operating and monitoring structure with appropriate system-supported accesses has not yet become available (see Section 11.2).

SPCs are also being used increasingly for plant automation in the field of process engineering. The starting points are often logistical side areas such as formulating lines, packaging lines, and high-bay warehouses. Starting from these applications, SPCs are spreading into chemistry-related areas. Especially in small and medium-sized plants, SPCs are often preferred to decentralized process monitoring and control systems because of their lower hardware costs.

Although such SPC-based solutions are often more expensive than complete distributed control systems when a total cost analysis including engineering costs for design, maintenance, and technical support is carried out, the low cost of adopting them may make them more attractive to plant management when investment funds are being sought.

CRT-aided operator control and monitoring features are available for SPC systems (see Section 11.2). Generally intended for use at individual workstations with limited quantity structure, these devices offer good functionality. Problems arise in larger systems with coordinated multistation operation, increased availability requirements, and central system services (e.g., network clock synchronization).

The separate design of SPC automation functions, communications functions, and operator control and monitoring functions remains an unsolved problem. The lack of certain central functions that would be present in a process control operating system has proved especially serious in SPC-based systems.

Integrated Decentralized Process Control System. The development of integrated decentralized control systems began with the control of large continuous process plants. In contrast to SPCs, the initial motivation was not so much the need to increase the degree of automation as the wish to improve functionality at the individual-function level by making design and installation simpler and cheaper and by making operation and monitoring more straightforward.

The starting point came when discrete-device technology ran into its quantitative limits. In this approach, each individual function is implemented in a separate, individual device; every motor has its own start button, its own run light, and its own contactor control. Figure 244 (see next page) shows a control panel with discrete devices, which are wired with electrical signal lines on the back.

The increasing number of individual functions and the presence of up to 50 control panels in central control rooms meant that an immense collection of controls and indicators had to be put together, creating space problems and also difficulties in comprehensibility. The primary task of the plant operator was to maintain a steady watch over the continuous process. To read the instruments, the operator had to walk along meters of panel bays.

The main goal of the decentralized process control system was to replace this discrete technology with a system combining the advantages of distributed structure and easy operation with the advantages of centralized data management and easily understood, display-supported operation and monitoring.

Figure 245 (see next pages) illustrates the component structure employed in decentralized process control systems. The distributed com-

ponents contain the automation functions for the individual plant areas. They are organized in parallel with the process. The central components contain operator control, monitoring, archiving, evaluation, and central coordination functions [581–583].

Figure 244. Discrete-device technology
Front and back of a control panel

From the very first, decentralized process control systems were characterized by ease of design and effectiveness of communications between process-level components and central control and monitoring components. Distributed systems have the following features: high-availability redundant bus systems, components that function reliably, low error rate in component design, and good technical support at the component level.

An important property of process control systems is the functional-module approach, in which software modules are handled in the same way as discrete devices. Functional modules can be inserted, switched on, removed, and connected to other functional modules while the plant is on stream. These properties result in simpler and hence cheaper design as well as high system reliability.

The operator interface of functional modules is designed to correspond to the discrete-device operator interface. Because of the similarity in operating properties, operating and maintenance personnel quickly learned to work with the new technology. This was an important reason for the successful introduction of decentralized process control systems over a broad front.

The successful introduction of distributed process control systems led to a demand for a higher degree of process automation. Concepts that have come to the fore in recent years have led to the integration of higher-order control functions, up to the level of recipe control and plant management, into the structures of distributed process control systems (see Chap. 2).

Intelligent Central Systems with Unintelligent Peripherals. The basis for this line of system development is the technology of process control computers, which became available for industrial service in the 1960s, that is, before stored-program systems and decentralized process control systems. Their introduction was greated with a certain technological euphoria, and due to the lack of alternatives this approach was adopted for the full range of plant automation, operation, and monitoring tasks. However, this concept was unsuccessful because of availability problems (due to the centralized structure), the fault susceptibility of the computers then in use, and the fact that both the hardware and the applications software could be supported and serviced only by specialists.

Figure 245. Component structure of a distributed process control system

Today, the only situations in which this concept is used are those where high-quality functions are required sporadically and access to installed monitoring and control systems is not possible. An example is the case of mini-plants and pilot plants, where availability requirements may not be high but it is necessary to test higher-performance control algorithms, implement model-based measuring techniques, or evaluate particular data. Furthermore, in research-level activities, personnel are often able to operate a process control computer themselves.

On the whole, however, this technology is declining in importance. It is increasingly common to use small, decentralized process monitoring and control systems or SPC-based systems for the control and operation of pilot plants. Special "research" functions can be implemented and tested on networks of flexible process control computers.

Structural Models. A process monitoring and control system is a complex pattern made up of many object classes; it can be structured in a wide variety of ways. As a result, a system description is difficult to understand and is always incomplete. Individual features can be explained only from a certain viewpoint, with other aspects being ignored. Nonetheless–and this is precisely the art of structural analysis–all aspects must be equally kept in view.

To provide a framework for the properties briefly discussed in the sections that follow, the most important structural models and the most important ways of looking at a process control system are described briefly.

Figure 246. The building-block model

Building-Block Model. The building-block model represents the structure of a system unit in terms of disjoint elements and connections (Fig. 246). This model is generally applicable;

it can be employed, for example, to describe the structure of mechanical, electrical, and functional system units. The building-block model plays an important role in the structuring of process control systems.

The building-block model has some properties that set it apart from general system decomposition and aggregation schemes (see Section 2.2, Fig. 2):

- Nesting principle: Each element used in building up a system unit is completely and exclusively allocated to this system unit. It is, so to speak, "built into" the system unit and is no longer available outside the system unit.
- External interfaces: Each element and each system unit exhibits its properties at certain well-defined external interfaces (e.g., electrical terminals, functional module inputs/outputs).

External connections are possible only through these interfaces, which can in turn relate it to various worlds. A compact controller, for example, has terminals as its electrical interfaces, displays and buttons as its human–machine interface, and bore holes for mechanical mounting.

- Implementation background: Building-block models describe realizable system structures. Hence it is not meaningful to define fictitious (dummy) elements with no realistic background and thus to built up fictitious systems. Instead, the objective must be to identify elements such that they are realizable but also represent manipulable units in the context of the overall structure.

Building-block models are an effective aid to describing the structure of system units of all types. In process control systems, they are well-suited to describing the structure of the hardware, describing the structure of the logical components, and describing the structure of the system and applications software.

Types, Roles, and Functional Units. When one speaks of a system unit or a building block, one must bear in mind that the unit referred to is a self-contained object that can be examined from various standpoints: role (function), functional unit (device; see Fig. 247), type of role, and type of functional unit.

When a control system manufacturer refers to its control system, it means the functional types offered. The design of a control structure means interconnecting functional units. These units correspond to roles that are selected from a list of well-defined types of roles. Ultimately, what is installed are functional units. This distinction is just as important for design and commissioning as it is for the overall understanding of the system. The relationships are shown schematically in Figure 247.

Figure 247. Roles and functional units

Functional units are the concrete devices, components, or software modules that actually perform a function.

The type of functional unit describes the essential qualities of a functional unit. Manufacturers' catalogs list, for example, the types of functional units available. If a catalog lists a P-REG compact controller, then one can order x units of this type. The manufacturer will then deliver x functional units of this type.

The type description of functional units goes beyond the purely functional description, taking in electrical properties, overall dimensions, weigths, prices, etc. The functional properties are a subset of the type properties of the real functional units.

Roles are fictitious functional units. An example of a role is flow controller F 1 in plant section B 12. This role can be defined–and used in building up the role system–independent of which functional unit (i.e., which device or software module) will later fulfill the role.

The model employed here specifies that each role is of a certain type. The type defines all the essential properties of a role. Obviously, any

number of roles of the same type can be defined in a plant.

Role systems are systems built up from discrete roles. In structure, role systems correspond to the building-block model. A functional role system is illustrated in Figure 248. This role system describes exclusively functional properties. It can be implemented with a wide variety of technologies involving a wide range of functional unit types, for example with software modules or in discrete devices. There are also more concrete formulations of role systems. For example, the control panel shown in Figure 244 can be thougth of as a concrete instance of the functional role system illustrated in Figure 248. In this role system, the roles are established much more fully. The description of each role includes not just functional properties but also electrical and constructional properties. These definitions can be made concrete if only functional units of a certain type are considered for its implementation.

Figure 248. The system of roles

Section 7.5. gives a detailed account of how role systems are built up, concretized, and implemented.

Hierarchical Structural Models. The object worlds of a process monitoring and control system can be arranged in hierarchically related functional levels. Each functional level represents a level of abstraction on which certain functional elements are available and certain tasks (or functions) can be carried out (see Section 2.2).

The modeling of a process control system involves not just one hierarchical structure, but hierarchical structures based on various criteria.

- Operational levels: The hierarchical structure of the operational levels includes interfaces for
  - The control system manufacturer who develops the system
  - The project engineer who configures the process control system for the specific application
  - The plant operator who ultimately guides the process

Figure 249 illustrates such a structure. The lowest level is the base system level, which contains units and functionalities provided by the control system manufacturer, that is, not specially developed for the control system. These might include PCs; workstations; operating systems such as DOS, UNIX, or VMS; database management systems such as dBase, Informix, or Oracle; and all the hardware not specially designed for the control system.

Figure 249. Operational levels

The second level contains the process control operating system. This level makes up the functionality of a manufacturer's control system. The user receives its units and functionalities when the control system is delivered.

The third level is the process control level. It is custom-designed and is available to plant management for active control of the process. It

satisfies all requirements on the control system as set forth in the project specifications.

In the model just described, the various levels are regarded as dense. This means, for example, that the designer does not need to access any level other than the process control operating system level (such as the base system). The operating system can include any required elements of the base system in its functional scope.

Thus the levels of functional abstraction correspond to self-contained working platforms. An important criterion for assessing a process control system is the functionality of the process control operating system level. Functional elements not available on this level must be programmed by the designer as required (see Figs. 16 and 17).

Figure 250. Virtual machines in a process control system

- Virtual machines: The execution functions necessary for the accomplishment of the tasks imposed can also be arranged in a hierarchical model by analogy to the operational levels. During its execution a function makes use of functions of the lower levels. The result is a system of virtual machines, each of which (as shown in Fig. 250) offers the higher-level functions an interface with certain services [584].

The hierarchical structure of execution functions is crucial for the internal implementation of program structures as well as the startup/restart behavior of the system.

At this point it becomes clear that the hierarchical structures illustrated are not to be viewed simply as fictitious structures but as concrete conceptual and real structure-generating programs. This is true of all the organizational schemes presented here.

According to a bottom-up principle, the functions on one level can be implemented with functional elements made available by the next lower level. In this way, more complex functional elements can be created and, in turn, made available for use by higher-level functions.

- Communications protocols: Communication between two applications can also be represented by a level model. Each protocol level corresponds to a "virtual medium" having certain properties, which the next higher protocol level can utilize in implementing its functions. A well-known scheme is the OSI reference model [585], which consits of seven layers and the overlying user functions and user data (see Fig. 296):
  - 7 Application layer
  - 6 Presentation layer
  - 5 Session layer
  - 4 Transport layer
  - 3 Network layer
  - 2 Data link layer
  - 1 Physical layer

  The structure of the communications layers (levels) is discussed in Section 7.2 for the example of systems communications and then described in general and comprehensive terms in Section 8.4.
- Process control: Process control tasks can be arranged into a hierarchical control model. In broad terms, the control model can be broken down into the following hierarchical levels: process control level, production management level, and corporate management level (see Section 2.3, Figs. 31 and 32).

The process control level can be divided into the following sublevels in accordance with the model of Section 4.5:
- Action level
- Group control level
- Individual control level
- Channel/signal level

Viewpoints. In the structural analysis of a process control system, the diverse viewpoints of the teams involved must be taken into account. For example, the following aspects are among those that must be considered:

- Development
- Sales
- Plant management
- Design
- Plant technical support and maintenance
- Device management

Each group represented by a viewpoint has an interest only in certain objects with certain properties. It does not make sense, however, to develop an isolated model from each individual viewpoint, covering only the objects of interest. Instead, it should be possible to relate all viewpoints to a single building-block model of a process monitoring and control system. What is needed are balanced model structures that will yield a useful mode of organization for all groups involved.

7.2. System and Component Structure

Overview. A decentralized process control system consists of individual components connected to one another through a system bus. The division of labor among the components varies in organization from system to system. One general distinction is between process-level or local components and remote components. Any component that has an I/O interface to the field is regarded as local, while any component that has no I/O interface to the field is considered remote. Figure 245 illustrates a typical functional structure.

Process-level components are generally organized in the same way as the plant. Each plant section is permanently assigned to a local component which controls and monitors the plant sections assigned to it. The component is autarkic (self-sufficient) and viable in the sense that it can perform its control and monitoring tasks independently. The result is a typical decentralized structure for process control systems as shown in Figure 251.

Remote components embody functions that are not directly a part of process-level control and monitoring. Examples of such functions are central operator functions, archiving functions, evaluation and interpretation functions, logging functions, production control functions, recipe management functions, and also engineering functions and diagnostic functions [581].

Figure 251. Organization of local components in parallel with plant organization

This division of labor can be modified from case to case. Many systems still have "entry-level" versions in which design functions, operator and monitoring functions, and archiving functions, for example, are integrated into the local components. Such a local component can be used alone, with no remote components. The introduction of economical remote components based on PC solutions has led to a perceptible decline in the use of such discrete component systems. In future, local components will perform only control and monitoring tasks, and even entry-level versions will feature a separate, small remote component.

Local components. A local component consists of a central unit and a peripheral unit, which in turn consists of peripheral or signal modules (Fig. 252)

Figure 252. Coupling of field signals by signal modules

Peripheral (signal) modules differ in functional form and can accordingly be placed in four categories:

1) Intelligent discrete control modules, which completely match the functionality of an individual control unit
2) Straight interface modules, which serve only as signal converters
3) Subsystem connection modules, with which subsystems can be linked
4) Field bus modules, which connect intelligent actuators and sensors through a field bus

Intelligent peripheral modules include, for example, controller modules, metering modules, and control modules specific to motors and other devices. The functionality of the individual control level as a whole can thus be realized by separate, independent modules. This added decentrality does, however, have tradeoffs both in cost and in space requirements. If intelligent modules are not absolutely necessary for reasons having to do with the scanning rate or special availability requirements, they are not used at present; instead, their functions are implemented in software in the central unit of the local component. The function of the peripheral unit is thus reduced to simply the input and output of signals, which can be achieved in compact fashion by using multichannel interface modules. For example, input modules are needed in order to feed and read two-wire transducers; to process the signals from NAMUR initiators, strain gauges, and mechanical contacts; to acquire and linearize thermocouple and Pt 100 signals; to handle multirange frequency inputs; and to process 0 (4) – 20 mA, 0 – 10 V, 0 – 24 V, BCD, and other input signals from units. The corresponding output modules provide the following functions: output of current/voltage signals, possibly into standard loads (up to 24 V); power outputs for solenoid-actuated valves; floating outputs; pulsed outputs for integrating positioning drives; and so forth.

In process control engineering, it is important that terminals always be floating or isolated. Inputs for intrinsically safe measuring circuits are a desirable option.

The conversion of measurements and control information to electrical signals can be relocated into local hardware by using field multiplexers. These devices still provide conversions to and from standard electrical signals, but in this case the operation takes place in the field rather than in the control room.

Subsystem coupling modules allow the connection of intelligent subsystems such as scale controls, converters, process analyzers, press

controls, filter controls, and other machine-specific controls. In most cases, subsystem coupling functions support serial point-to-point connections, but there are also bus-type structures with the process control system as permanent master.

Field buses provide logical connections of actuators and sensors with no conversion to static electrical signals. Numerous proposals have been made for defining and standardizing field buses and marketing them as standard systems. Up to the present, it has not been resolved which solutions will finally prevail in the marketplace. Figure 253 illustrates some important field bus systems [586]. In addition to national criteria and corporate tactical decisions, differences in functional requirements also contribute to difficulties in the standardization of field buses.

The *central unit* of a local (process-level) component generally consists of a special microprocessor, ca. 1 – 4 MB RAM, and a connection to the system communications. Additional modules are available in many systems for implementing a local operator control and monitoring function or to provide a background memory for archiving purposes. It is important that the local component should have a process control operating system and be integrated–with its object and communications structure–into the overall system. This means that the system functions of the local components permit, for example, the support of central design and the provision of server services for the operator control, monitoring, archiving, alarm, and message generation functions.

Remote Components. Figure 254 illustrates the tasks (functions) to be performed by a process control system independent of how the system is implemented [587]. Two basic structures exist at present:

- First-generation control systems have no information model that applies throughout the system. The individual components are specially designed and optimized for the tasks they implement. Thus, operation, computer, and engineering components generally have different system architectures and can neither be configured and maintained in a uniform manner, nor controlled through a consistent user interface.
- Second-generation process control systems have an information model consistent throughout the system. Data processing management (operating system, data handling, communications, operator interface) for all remote components is implemented in the most uniform way possible (Fig. 255).

The advantage of this concept is that each function can, in principle, be performed in any component. The allotment of required functions to components in a specific case is carried out with regard to the following criteria: decentrality, uniform processor loading, minimal data exchange, and realization of certain redundancies. The operator interface is uniform across the system. Any function in any remote component can be accessed from any terminal. Thus, from a given terminal, one can configure a component x in the system, use an operator function to perform a certain action in a component y, view the archive stored in component z, and effect an input to the production control system located in component z. Which interventions are possible in a particular case is governed solely by access authorization. The extent to which the human – machine interface is consistent between packages will depend on the state of development of the individual system packages. The need for a consistent concept, however, requires a consistent systems approach from the outset. In small plants, this concept has the important advantage that a modest hardware platform can make available the entire system functionality; thus the hardware governs primarily the realizable quantity structures (quantitative) rather than the functions that can be performed (qualitative). If the requirements are increased, the power of the system can be adapted to the new tasks by the modular addition of hardware. The presence of a consistent information or data model is, however, an essential prerequisite (see Chap. 2).

System Bus (see also Chap. 8). The system bus is the nerve center of the process control system. The following services, among others, are performed via the system bus:

- Continuous delivery of data from local and remote components to the monitoring functions

Figure 253. Classification of field bus systems

Figure 254. Ideal structure of a process/production control system

- Transmission of operator commands, acknowledgments, and instructions from central process and production control functions
- Provision of required data to the central archive
- Delivery of messages and alarms to the message receiving services
- Object manipulation and object information to assist central engineering
- Loading of actions (production specifications, execution specifications)
- Internal update functions when individual components go out and are restarted
- Temporal synchronization

The system bus of a process control must have the following technical qualities:

- High availability
- Insensitivity to electrical and electromagnetic interference
- Deterministic behavior, even when under load
- Open architecture (compliance with international and de facto standards)
- Hardware and software capable of adding or deleting subscribers while bus is in operation

Figure 255. Process control system with continuous operating system platform for distributed use

The following features are possible ways to meet these requirements:

- Use of optical fibers for data transmission. Optical-fiber technology permits high transfer rates even in large-scale networks. Electromagnetic interference and potential problems in the bus system are physically excluded.
- Transparent redundancy of medium. The required high availability is possible only if the transport medium is redundant in design. Its redundancy must be transparent; that is, higher communication levels must not be affected by a switch from a pathway to the redundant pathway.
- Use of token-passing protocols. The use of the token method for transfers means that every subscriber can send important messages within a fixed length of time, even when the bus is heavily loaded.

Currently there are no standard system buses having these implementation features in the middle- (ca. 1 Mbit/s) and high-performance (ca. 10 Mbit/s) ranges. It is therefore no surprise that all system buses now available, while they do use standards for certain levels, still represent manufacturer-specific solutions on the whole.

Unfortunately this commercially important range of medium and high transfer rates is not currently experiencing any development that could lead to a standard solution with the properties needed in a process control system. It appears that there is still some time to wait for an "open" system bus for use in process control engineering.

The only hope at the moment is FDDI in the ultrahigh-performance field. FDDI has some prospect of acceptance as a general standard and has all the technical qualities expected in a system bus for process control systems. It is currently handicapped by its very high cost and by the space and power requirements of the interface groups to handle the high transfer rate (100 Mbit/s). Nonetheless, this approach is going to be a focus of attention in process control engineering circles.

The following comment should, however, be made on the evaluation of data-transfer rates.

If the transfer requirements imposed on a system bus in a process control system for controlling the process are considered, it can be seen that a gross transfer rate of 1 Mbit/s is sufficient for such tasks, even in larger networks. The net transfer rate strongly depends on a choice of individual transmission services and the network data distribution model.

Bottlenecks can occur, for example, when archives are updating one another, when static image information is being transmitted over the bus, or if an unsuitable data model has been chosen. A typical example of a transfer-intensive data model is the centralized display of all local component status information at remote component locations.

In the assessment of a bus system, therefore, the gross transfer rate is less important than a well-thought-out model of data management and data sharing on the network.

Component Structure of Commercial Process Control Systems. Figures are intended to explain the component structures of several process control systems. The selection is meant to provide examples and does not reflect either market position or technical ranking.

In Figures 256 – 269, the notation used for the components complies with the manufacturers' product designations.

The following symbols are used for functional packages:

AR Archiving functions
CO Control functions
EN Engineering functions
GA Gateway functions
IO Process input/output functions
OP Operator functions
PR Protocol (reporting/logging) functions
CD Coordination functions

Note that some functions relate to not a single component but several. In such cases, the packages are separated into client and server portions and a letter (C, S, or L) is appended in parentheses:

(C) Acts in the system as client of the function
(S) Acts in the system as server of the function
(L) Function is implemented locally with no involvementof system communications

The codes C and S are used only for components that support the function on the system side, that is, when communications need not be separately programmed.

Examples:

Engineering Functions. The engineering component in which design activities are carried out acts as a client in the system. The target system designed by the central engineering function acts as a server in the system. The engineering station would thus have (C) appended to its symbol, while the target systems designed by the central engineering functions via system communications would have (S) appended. Locally configurable components would have an (L).

Operator Functions. Functions available troughout the system provide for operator control, monitoring, and the transmission of messages and alarms. With these functions, information is shared between individual applications in the target system and the operator (via the human – machine interface). The display and operator components act as clients, while the target component in which the operation takes place or in which a status is interrogated is regarded as the server.

Figure 256. Functional structure, ABB Master

Figure 257. Functional structure, ABB MOD 300

Figure 258. Functional structure, AEG Geamatics P

If one examines the structures in detail (see Figs. 256 – 269), one sees that most of the process control systems illustrated offer extensive systems solutions for the handling of local components. The major shortcomings are in communications between remote components. Server properties are largely lacking in these remote components. In other words, remote components often cannot be centrally designed (configured), and the normal operator control and monitoring functions do not make it possible to operate and monitor applications in other remote components.

Redundancy. The following concepts can be applied to redundant design:

Necessity of redundancy (see also Section 10.4)

The availability of the process control system depends on the frequency and duration of failures of its components. In general, when the process control system or a portion of it fails, the production plant or the respective plant section also fails.

If an especially high availability is required of a plant section, or if the failure probability of this plant section must be particularly low, the local components controlling it must be designed with redundancy. However, this is an exceptional case. In many situations, it is acceptable for individual plant sections to fail. Production can be briefly interrupted, or plant sections redundant from the production engineering standpoint can be switched over. The decentralized structure of

Figure 259. Functional structure, Bailey INFI 90

Figure 260. Functional structure, Eckardt PLS 80 E

the control system means that the failure of one local component affects only one of the redundant plant sections, provided the allocation has been chosen correctly. Here, the process control system need not exhibit additional redundancy.

In the case of continuous processes that run nonstop for 3 – 5 years, as is common in some industries, scheduled maintenance of the monitoring and control hardware becomes a problem. The performance of scheduled maintenance generally involves removing modules, while inspection entails removing entire system portions from active service. Redundancy is essential if this is to be done.

Figure 261. Functional structure, Fischer & Porter DCI System SIX

Dispensing with integrated operator and monitoring functions in the decentralized local components makes it necessary to have a redundant bus system with redundant implementation of operator functions in the remote components. Back-up operation with local intervention at the local components is generally no longer possible.

Modular redundancy concept

In the modular concept, the decision whether to make a unit redundant or not is made separately for each unit in a system. Three points favor modular redundancy:

- Redundancy is only desirable for well-defined, self-contained units
- Modularization creates redundancy nodes, which separate the individual redundant units from one another and increase the availability of the system
- Redundancy is expensive and it is therefore sensible to employ redundant design only where necessary for a specific application

Figure 262. Functional structure, Fisher Controls PROVOXplus

Figure 263. Functional structure, Foxboro IAS

Figure 264. Functional structure, H & B Contronic P

Figure 265. Functional structure, Honeywell TDC 3000

Figure 267. Functional structure, Siemens Teleperm M

Figure 268. Functional structure, Westinghouse Controlmatic WDPF II

Figure 269. Functional structure, Yokogawa Centum XL

Figure 270 illustrates a modular redundancy concept for the system bus and local (process-level) components. This is an instance of transparent redundancy of the medium, which means that the individual data-transfer and processing units implement redundancy in such a way that higher-level system and user functions do not see it logically.

Figure 270. Modular redundancy concept

The situation is different in the area of remote components (i.e., on the "client side"), where standard components (workstations, industrial PCs) are employed in a nonredundant system structure. Redundant design is aided by special functions in the process control operating system and general system services and is ulti-mately realized in the structure of the user functions.

Quality of changeover to redundant units

The redundant layout of units means that if a unit A fails, it is possible to change over to another unit B which continues to implement the required functions.

An ideal changeover is as follows:

- A malfunction in A is correctly detected as soon as it occurs, and the changeover takes place before a single datum in A is altered
- Prior to the changeover, B is in exactly the same state as A
- The changeover takes place with no time delay
- The changeover is "bumpless"

This is, of course, an idealization. In real systems, a number of problems arise:

- Detection of the Malfunction. A malfunction can be detected by self-diagnosis in A itself or by external monitoring. External monitoring systems are commonly based on the comparator principle. In a 1-out-of-2 redundant setup, however, localizing the malfunction is a problem. If the two units do not agree, which is wrong, A or B? Another problem

is the time between the occurrence of a malfunction and its detection. Has A improperly changed its state in this interval as a result of the malfunction?

- Synchronization of B. B must begin working at the point where A quits. The question is how B, at an acceptable cost, can track A so as to hit the starting point as exactly as possible. The designer must then ask: How is the synchronization to be done? If A and B are clock-synchronized, or if there are synchronization points in the software, what deviations in the instantaneous states are tolerated and what deviations are unacceptable? Are data transfers in progress terminated and restarted, or is control passed "on the fly"? And so forth.
- Changeover. When the changeover takes place, all communications links of unit A are broken and replaced by links of unit B. The following problems arise at this point: How is the logical changeover accomplished? How long does B take to come into sync? How long will it take before all partners of A/B have dropped the old connections and made the new ones? Is the changeover automatic or manual? Does unit B remain on permanent standby, or must it be turned on or even fetched from storage?
- Restart. Once the malfunction has been corrected, how is the automatic restart of A (up to hot standby) supported without impairing the function of B?

The implementation of a modular redundant process control system is essential if the stated requirements are to be met. A good redundancy concept is the mark of distinction in a process control system. The questions stated under "Quality of Changeover to Redundant Unit" are not intended to lead the designer to a particular solution but rather to indicate the complexity of the problem and afford some warning against obvious but half-baked solutions.

Electrical and Mechanical Design. Process monitoring and control systems must function reliably, feature robust construction, and be adaptable and modifiable even while in service. Special importance therefore attaches to the mechanical and electrical design of these systems.

Mechanical Design. Local components are generally rack-mounted inside steel cabinets. Central modules are located in one plug-in unit; peripheral modules, either along with the central modules or in additional plug-in units. A module can be a simple card or an enclosed rack-mount device. The technique used to connect signal lines leading to the field varies from system to system; plugs on the front and backside are common, as is direct wiring to terminal posts or screw terminals in a special terminal bay.

An important mechanical design question is whether the cabinet must be accessible from one side or both sides. Practice has shown that access to the back of the plug-in units is necessary. This can be achieved by leaving a walkway at the back or, when this is not possible, by using a swing-out cage.

Remote components must also be considered in the course of mechanical design. Because these are generally off-the-shelf hardware, they must be mounted in an appropriately stable and secure way, either in control room panels or in properly equipped cabinets in the process control rooms (see also Sections 5.3 and 10.7).

Electrical design includes the overall electrical behavior of the process control system components. Important aspects of electrical design are power supply, isolation and earthing, protective enclosures and safety requirements, electromagnetic compatibility, and response to external conditions such as climatic, seismic, and chemical effects (see Section 6.4).

- Power supply.
  The process control system is responsible not only for controlling the plant but also for monitoring it. It is desirable to provide a highly reliable uninterruptible power supply for the process control system; this makes it possible at least to acquire and record information about the process and plant status even when power to the processing facility is interrupted. It is precisely these exceptional situations that make the process control system so vital as an information system (see Section 6.4).
- Isolation; earthing concept.
  A process control system communicates with a number of partners, some of them from different manufacturers. This is particularly true of local (process-level) components as well

as the subsystem and field areas. It must be possible to adapt the control system to the local grounding concept. The goal is thus a control system "open" from the grounding standpoint. This requirement will be fulfilled if each input and output in the process monitoring and control system is electrically isolated. The earthing concept determines which potentials are connected in a specific case (see Section 5.3).

- Protective enclosures and safety requirements.
  Process control systems are electrical systems and must satisfy regulations on shock-hazard protection and protection against the ingress of solid bodies and water. These regulations are based on IEC 529 (protection against foreign bodies and water) and IEC 536 (shock-hazard protection). In process control systems it is particularly important that the following sections be spatially separated from one another: low voltage; functional extra-low voltage with safe separation (PELV as specified in DIN 100, Part 410); and intrinsically safe circuits.
- Electromagnetic compatibility.
  Process control systems are operated in an electrically harsh environment. In many situations today, these systems are located next to static converters and other power electronics, in the same room or even cabinet to cabinet. Operating personnel use handheld radios when the cabinets are open, and the rebranching field cables can pick up interference. Therefore, electromagnetic compatibility is a special concern in process control systems. Electromagnetic compatibility is a measure of resistance to noise resulting from
  - Static discharges (IEC 801-2)
  - Electromagnetic fields (IEC 801-3)
  - Bursts [IEC 65(Co)39]
  - Hybrid voltage transients [IEC 801-5 (Draft)]

Other guidelines, recommendations, and standards have been issued by NAMUR and DIN; see, for example, [588–590].

For each device, the severity of the effect can be measured and classified. Four classes can be defined:

1) No impairment of operation or function
2) Momentary impairment of operation or function, self-correcting
3) Momentary impairment of operation or function in which restoration of service requires resetting or operator intervention
4) Permanent loss of function resulting from damage to the device (or its components)

In general, it is expected that the maximum effects under moderately severe testing (IEC Severity 3) will fall into Class 2.

- Other conditions.

This heading takes in all other environmental effects that might lead to impairment of the functioning of the process control system. They include, among others:

- Temperature and humidity
- Seismic stress
- Chemical attack (e.g., acidic gases)

Environmental conditions are defined and classified in IEC 721; test methods are set forth in IEC 68.

7.3. Process Control Operating System

A process monitoring and control system is a distributed system in which modular control structures are managed and executed in the most efficient way possible. This applies in particular to the local (process-level) area. The process control system should make it easy for the user to work with a modular system (as illustrated in Fig. 248) in a similar way to a system based on discrete devices.

For example, it should be possible to install or remove a module without interfering with the operation of other modules, and to make or break a connection or modify a parameter value while the system is in operation. Another important point is reliability. For example, the making of a connection should not inadvertently cause internal interference with a modular algorithm, while the manipulation of a module should not result in the accidental change of a parameter value in another module.

These requirements can be satisfied only if the process control system has an operating system with appropriate object manipulation and object-oriented programming capabilities; the operating system should also support the creation of modular software structures.

Figure 271. Procedure-oriented and object-oriented modular technologies

Three approaches have been taken to implementing these requirements.

In the first approach, the entire "modular intelligence" is concentrated in the design system. The local components responsible for control system operation do not have a modular structure. The design system makes a translator run, generating a transparent code from the objects managed, and loads this code into the local components for execution. The advantage of this technique is that the requirements on local components are modest; the local components can be structured easily and thus economically. On the whole, however, this concept has not yielded any satisfactory solutions. The main reason is that changing a single object requires retranslation and reloading of the entire program. Such a system is extremely resistant to changes.

When partial translation or partial loading is desirable, the design system must have a detailed knowledge of, and partial authority over, the data organization of the local components. The cost of developing such a design system is high and cannot be controlled, especially when the local components are further developed.

For these reasons, all successful SPC (stored-program controller) systems are decentralized process control systems that include management structures for objects in the local components themselves.

It is necessary to distinguish between the "procedure-oriented" modular approach used in SPC systems and the "object-oriented" modular approach used in distributed process control systems.

Figure 271 illustrates the difference. In the procedure-oriented modular technology, data modules and procedure modules are the objects. Distinct procedure modules communicate through data modules. The procedures describe certain data elements of the data modules, which in turn are read by their procedures. The connection does not exist as an explicit object. In this method, the system does not afford protection of access to the data areas; that is, all data can be read by any procedure, and also written if the procedure is write-enabled.

The right-hand part of Figure 271 shows the object-oriented modular technology, where data and procedures (here also called methods) are combined in a single module that can be handled only as a whole. Data sharing takes place via connections between the module connectors. Direct writing and reading of internal module data is not possible at all. The only way to access these internal data is locally, through the methods inherent to each module.

It is important to maintain the distinction between these two technologies. In practice, many misunderstandings arise when the term "modular technology" is used. In the SPC world, procedures are also referred to as "functional modules" and data as "data modules."

The forms of office organization shown in Figure 272 illustrate the properties and applications of the procedure-oriented and object-

Figure 272. Examples of procedure-oriented and object-oriented setups

oriented approaches. On the left, Müller and Schulz work together in a project team. They sit across the table from each other, in a room containing a cabinet with a shared set of files. This arrangement corresponds to a procedure orientation. Müller and Schulz correspond to the procedures; the set of files, to the jointly available and processed data. This form of organization has the advantage that every worker has quick, direct access to the common data. The setup does, however, require intensive communication and agreement between the two team members: each must know exactly what the other is doing and what data are being changed. While this organizational form is feasible for small, easily overseen units, in larger and more complex structures it is no longer possible.

More complex structures require local data safeguards. Such a form of organization is shown on the right in Figure 272. Maier has his own set of documents, to which only he has access. No other team member can enter his office to view a file or enter anything in a file; anyone wishing to obtain such information or make such changes must ask Maier to provide information or make an entry. Maier himself decides whether and how to respond to this request. Maier and his data form a unit that, as a whole, performs certain tasks. This form of organization corresponds to an object orientation.

If the parallel is drawn to process control systems, it becomes clear that the traditional approach in SPC-based systems–which historically arose from small automation systems with fast access requirements–is procedure orientation. Decentralized process control systems, on the other hand, were designed for large, complex networks from the very beginning, and in these systems the object-oriented modular approach predominates.

The remainder of this section will describe the basic properties of a process control operating system supporting an object-oriented modular system.

Software Modules. One characteristic of a modular system is that a module–with all its parts, data records, connectors, and methods–is treated as a unit. In production service, from the communications standpoint, the module can be identified by a single reference.

Such an object-oriented modular concept can be implemented in either of two ways: by realizing the modules as flat, completely autonomous objects, or by realizing them as entities belonging to a class hierarchy.

Methods using discrete devices correspond to the first approach. Each compact controller has its own data storage, its own interfaces, and its own logic for implementing the PID algorithm. In a software-type concept, which follows the second approach, the modules are realized as instances of module types; this corresponds to a special, one-level abstraction scheme.

When it is realized in the functional system, each module is therefore split into two objects, a type object and an instance object. The type object contains the processing methods, a description of the data structure, and a description of the connector structure. The instance object (entity) contains the module name, the individual status information, and a reference to the type object.

This functional structure implies two properties that are significant for module handling in process control systems:

Figure 273. Software implementation of three modules of the type "controller"

- Type objects and entities can be created and loaded separately
- More than one entity can be defined for one type object

Figure 273 shows realizations of three controller modules. All three use the common type object "PID controller"; modules TA 12 L 1, TA 14 F 1, and TA 3 T 2 are three entities.

The creation and loading of types is an operation that generally calls for profound system knowledge and can be performed only by certain persons. In many process control systems, the user cannot create new module types with their own data structure, connector structure, and methods. The user must make do with the set of types provided by the manufacturer.

In contrast, it is very easy to work with instances under the software-type concept. Because all data structures, connector structures, and methods of a module are defined when the type is created, the instances need only be generated as data records, parametrized, and inserted in the processing sequence. These are simple operations, and in virtually every process control system they are supported by the operating system of the local components, even during production operation.

The software-type concept has proved effective for the handling, management, and sequential organization of the modular system in process control systems. In a variety of components, the concept has been embodied and optimized for the requirements of a real-time system with many objects to be processed concurrently.

Certain constraints relative to a general class hierarchy are unavoidable. They include the following:

- The functional system supports only one level of abstraction (entity – type).
- Type data are present in multiple copies and are thus not free of redundancy. The type data for a module are available locally, as loaded type objects, with respect to every processor.
- Each instance has a direct reference to the type object of its logical environment and knows what information it will find where.

As far as the external function of a module in the modular network is concerned, it makes no difference whether the module is realized as an autonomous object or as an instance of a type. In the software-type concept, the instances provide the external representation of the module with all of its properties.

Communications Network. A major task of the process control operating system is to manage and dynamically perform communications in the network of modules. Each module

has connectors serving as external interfaces, through which it exchanges information with its surroundings. All communications in the modular network can be depicted in terms of individual communications links, each between one module input and one module output.

From the applications standpoint, there are two basic forms of information exchange: the "get" relation and the "send" relation.

Figure 274 illustrates a *get* relation. B is interested in the present state of A and reads this state from A without feedback. Such a relation corresponds, in discrete technology, to acquiring a signal from an output terminal. A given output A can be read by various inputs.

Figure 274. Get relationship

In this kind of relation, only the recipient is interested in exchanging information. The recipient needs a state that another unit is furnishing as an output, and needs it as quickly as possible. Regardless of the concrete form of this transfer–a network may well contain sending and event-driven system services–the relation as seen from the user's viewpoint corresponds to a get relation.

Relations of this type lead to low-error-rate structures that are easy to reconstruct in dynamic fashion. The fact of access without feedback means that get connections can be made without further safeguards.

Within the component, a get connection corresponds to a read access of an output variable and, accordingly, can be implemented efficiently.

Many process control systems permit the treatment of get connections as objects in the local components, or at least get connections internal to a component. Their management and general implementation are taken care of by the operating system.

Figure 275 shows a *send* relation. Here one application has a functional interest in communicating something to another application. This would be the case, for example, when higher-level units transmit orders to lower-level units; where monitoring units have the task of automatically generating messages and alarms; or where operator control units wish to send a new control value to an application.

Figure 275. Send relationship

The attribute send here does not refer to the type of transmission; it represents the fact that the initiative and interest in data exchange is primarily on the part of the sender.

A send relation is characterized by the following features:

- The application behind connector C knows under what conditions C is to send what information to whom and activates connector C accordingly.
- The message from C leads to a write access in D; that is, the state of D changes.
- The associated service in D must therefore have a protective mechanism that receives the message, checks it, and performs the write only after successful checking. The protective mechanism checks both sender and content.
- To avoid unpredictable response times, the server service responsible for checking the message and processing it on receipt must be initiated as soon as the message arrives.

Figure 276. Instruction input connector

By way of example, Figure 276 shows an instruction input connector. When a message containing a new instruction arrives, the availability of the connector is first checked. If the connec-

Figure 277. Communications as a system service

Figure 279. Communications internal to a component

tor is available, it is then occupied. The message is next checked for formal correctness (type of message, variable types, etc.). If the result is positive, the message is correct. This does not mean that the instruction can also be accepted by the module in terms of its content. The receiving service therefore has a link to a part of the module method specially allotted to the connector. This checks whether the content of the instruction is permissible from the application viewpoint. If the result is positive, the instruction is finally accepted and written as a new effective instruction. The sender of the instruction is notified of the acceptance, or the reasons for nonacceptance, of the instruction.

Most process control operating systems also permit unprotected writing into effective module input areas. Some users make intensive use of this capability, transforming the process control system into a quasi-procedure-oriented system. This is not, however, in keeping with "good programming practice" and should be avoided whenever possible.

A process control operating system must have the goal, as illustrated in Figure 277, of managing all communications relations between connectors in the modular network as objects and embodying their implementation, as seen from the user's viewpoint, in a system service. Many process control systems already do this within a local component, at least for relations internal to the component. The critical relations, however, are those between connectors belonging to modules implemented in different components. Here the user must explicitly design (configure) the communication in many cases. For example, it may be necessary to integrate and wire certain LAN communications modules. The message orientation and the strict formalization mean, however, that the connector model will later enable the operating system to manage and execute connector-to-connector relations over the LAN.

As a consequence of the special two-level module → connector object structure and the client/server character of the relations defined, itis possible to make efficient use of MMI services (see Section 8.5) for imaging. Open communications (see Fig. 278) can thus become a basic feature integrated into a communications network extending over many components.

Connector-to-connector communications can thus be organized as a network-wide mes-

Figure 278. Connector-to-connector communications via the LAN

sage exchange system. A crucial point is that the simple local relations, with their efficient execution methods, are incorporated as an integral part of this overall system. If, as shown in Figure 279 (see next page), two applications are located in the same component, the process control operating system can implement connector-to-connector communications with optimized local access functions.

This technique can greatly increase the processing power of the execution system.

At the process (local) level, "get" relations within a component are the most frequent type of communications and are crucial for the loading of the communications network.

If all these relations were executed through a general message exchange system, the capacities of the functional units would be far too small. This level of performance can only be achieved by effective use of internal pointers and direct reading, both organized by the operating system.

Addressing. The objects and name spaces contained in a process control system depend on the organizational viewpoint and scheme. It is necessary, for example, to distinguish between the hardware viewpoint (component, module, unit), the access viewpoint (bus segment, subscriber, module, unit, connector, variable), the open communications viewpoint (VMD, domain, variable), the programming viewpoint (unit, connector), and the engineering viewpoints relating to the structure of the process plant, the breakdown of the process to be performed, or the structure of the production sequence.

Each way of analyzing the system has its own hierarchical name space, in terms of which the individual objects in the system so analyzed can be addressed. There are many mappings and assignments among the objects in various system breakdowns, and hence many object management structures and addressing options. These are not presented in detail here.

A question that is of interest, however, is addressing for LAN communications in the modular network. Most process control operating systems have not integrated communication via LAN into their module communications, and, therefore, either special communications functions must be installed (READ, WRITE, SEND, RECEIVE, . . .) or communications must be structured with direct, unprotected read or write access to the module variables.

Figure 280 shows one possible addressing scheme in the modular approach. The scheme is shaped by three aspects, which must be mapped into one another.

Addressing in the client is done from the programming viewpoint. The client connector wishes to make a connection to a certain server connector. The server connector is identified by its name and the name of the module (unit).

The process control operating system (OS) recognizes that this unit is located in another VMD and maps the requirements onto an MMI function. The unit is thus mapped into an MMI domain and the connector into an MMI variable in 1:1 fashion.

In the target VMD, the process control OS performs the MMI server functions and exchanges data with the server connector. The OS

Figure 280. Example of connector addressing via LAN with names

uses its internal access addressing scheme, for example the module number, unit number, connector number, and individual variable numbers.

This is just one possibility. There are others, such as access through abbreviated addresses. The important point for effective open communications is that modules (units) and connectors can be mapped 1:1 into addressable communications objects.

Execution Properties. An important task of the process control operating system is to control the sequence of module processing. In general, a module consists of a main method and various connector-specific methods.

The main method is started by a call to the module by the executive system. In process control systems, calls typically come in cycles at fixed time intervals. Each module can be allotted such a fixed cycle for itself. Cyclic method calling is independent of whether or not changes of state have taken place at the input connectors. Cycles of between 1 and 4 seconds are typical in process engineering.

Connector-specific methods are permanently allocated to the input connectors. They are started in acyclic mode when messages arrive at the respective input connectors.

Asynchronous Operation. The use of fixed cycles generates deterministic sequences between certain modules. Even so, the modular network as a whole must be regarded as a network of modules in asynchronous operation. The processing of a module can be interrupted, for example, by the processing of a higher-priority cycle sequence or by connector-specific methods started in acyclic mode. Furthermore, if module processing is shared among several processors, cycles of equal priority also run asynchronously.

Asynchronous operation results in data consistency problems:

- While one module is running, the outputs of other modules may change
- While one module is running, processing of another module may be interrupted, so that its outputs represent results from different cycles

These problems are not generally relevant. The output states requested must be as current as possible. Inconsistencies are not a difficulty for the processing algorithms. Applications requirements, for example in module type creation, may call for appropriate measures to insure consistency in certain cases.

The efficiency-oriented concept of process control operating systems manifests itself again here: avoidance of unnecessary management overhead.

Synchronization methods are available to insure the consistency of output and input data. However, they impose a substantial burden on the executive system and markedly impair the performance of the local components. Most process control operating systems purposely dispense with system measures to impose consistency. Note that all the devices in a discrete control system also function in asynchronous mode without consistency-insuring measures.

7.4. General System Services

A control system is expected to offer, as an integral feature, certain general system services for production operations. These should be implemented as firmware in the process control operating system (OS).

The pertinent services include the following:

- Communications and organization services for operation, monitoring, the generation of messages and alarms, archiving, and report creation
- Time management and network synchronization services
- Monitoring and diagnostic services for process control hardware
- Services supporting the changeover between redundant units and the matching of their states

Integration of these services into the process control OS by the manufacturer is necessary because only in this way can they be implemented in a meaningful way and performed with the necessary effectiveness.

Unfortunately, there are no standards governing the functionalities of these system services; the available, manufacturer-specific solutions differ all the way back to their principles. The user must consider the structure of these manufacturer-specific system services and fit the applications software to it.

A manufacturer-neutral design procedure is therefore possible only within narrow limits. In principle, this design approach is restricted to the configuration of certain processing functions with standard languages such as FUP, module language, and so forth.

This part of the configuration job often makes up only 40 % of the whole. The remaining configuration work must deal with configuring and parametrizing manufacturer-specific system services.

This section will describe in detail the tasks and contents of the system services. Each service is treated as an individual functional module.

Monitoring (see also Section 11.2). Processes are generally monitored by using color graphics displays. The interface can be based on standard solutions from the PC or workstation realm. The monitoring services provide the monitor interface with the appropriate video and status information. One monitoring service includes transmission of the state value from its source to the monitoring system, maintaining an internal state map (state or status image) in the monitoring system, and displaying the state value at the interface. Figure 281 shows schematically a monitoring service.

The monitoring system always displays the current state values. If a state is dynamically changing, it is important to display its most recent value. Past values and timestamps are not of interest. On arrival, each new value overwrites the old value on the screen.

Figure 281. Schematic diagram of a monitoring service
S = state; SD = state display; SIM = state image; STS = state transmission server; DCC = display and control component; LOC = local component

All monitoring interfaces are implemented by the monitoring system. The same holds for the display of archival data, messages, records, and so forth.

When the message log is displayed, for example, the message system is the source of the states displayed. The timestamp of a message is a state of this system and is retrieved and displayed by the monitoring system in the same way as any other state.

State Displays. A state can be displayed in a variety of ways, and standard interfaces offer all the possibilities. It is therefore a fundamental question of human – machine or human – process communication design how a state is represented in each particular case.

Figure 282 presents examples of ways of depicting a binary state. Often, a binary state is represented by a color change in a text field or by the presence of a mark. In flowsheets, the process state that the binary state represents is indicated symbolically. For example, a curved arrow or a color applied to the valve symbol can be used to indicate whether a valve is open.

Figure 283 shows several representations for an integer or floating-point value. Here, standard systems offer a wide range of easily implemented display options (see Figs. 372 – 380).

Maintenance of State Image. The various ways of maintaining the state image in the monitoring system give rise to basic differences in process control system data models.

Figure 282. Representations of binary states

Figure 283. Representations of a floating-point value

Important goals in managing and maintaining the state image (map) in the monitoring system include the following:

- Keeping the displayed states updated: The current value of a source state should be displayed within one second if possible (or at least within two seconds in exceptional cases).
- Rapid preparation of a new image with the proper state values: When a new image is selected, the image together with all updated states should be constructed within 2 s (within 4 s in exceptional cases).
- Minimizing the data transfer cost: In most situations, the state sources are not located in the same display and control component as the monitoring function itself. The required states must then be transferred via the bus. In large systems in particular, or when the depth of detail is great, measures must be taken to reduce the amount of data transferred.
- Minimizing the cost of preparing the state information in the source system: Some effort must be expended in the source system to prepare the state data and organize the data transfer. This extra work must be considered from the outset when calculating the load on the source system. Problems arise, in particular, when several display and control components are used, each with its monitoring interface and all accessing states of a relatively small local component, or when a change-driven data transfer service is implemented.
- Modular organization: The state image maintenance procedure must be set up in such a way that new images can easily be inserted in a monitoring system and an additional display and control component, with its own monitoring system, can be connected to the system communications at any time.

The simplest way to organize and maintain the state image for monitoring is by using a 100 % image in the display and control components (DCCs). All states that might ever be required for monitoring are held in every DCC at all times. This solution, which is practicable in small one-station systems, leads to performance problems in large multistation setups. If the possibility of insetting detailed state information is not to be lost, data transfer must be optimized, for example by selective or change-driven transmission.

Figure 284. Selective state display
SD = state depiction; DCC = display and control component; SIM = state image

In selective transmission (Fig. 284), only those states that are currently displayed are updated in the state image. The data-transfer load thus depends on the scope of the images currently displayed, not on the scope of all images configured. The image can be carried to any depth, down to the smallest details, without any change in the preparation and transmission load. Selecting a new image means a change in the set of states to be updated. This must also be reported to the source systems and new arrangements made there. The process control operating systems of the components involved must there-

fore include an effective service for this purpose. Process control systems with the option of selective state images can generally be upgraded to large multi-workstation installations without difficulty.

The second possibility is change-driven transmission. In normal operation, many states undergo changes infrequently or not at all. This leads to the possibility of transmitting only when a state has changed significantly. The number of data to be transmitted under normal conditions is drastically decreased. The detection of state changes in the source system presents a problem. Any change of state in a binary value is significant, but in the case of an integer or floating-point value, a change is only significant if it exceeds a certain set distance from the old value. Detecting deviations leads to a perceptible load on the source system. A further drawback to change-driven transmission is that load fluctuations are difficult to calculate. Large numbers of switching operations take place in the plant precisely under critical conditions, so that there are simultaneous changes in nearly all process parameters. A change-driven system must be designed for these extreme peak loads.

Operator control refers to the specification of values by an operator via the system's own human – machine interface. The following units are involved:

- The operator, who communicates with the operator control system through the input device.
- The operator control system, which handles the selection and execution of instructions.
- The instruction acceptor, which checks the value entered. If the result is positive, the value is accepted and furnished as a new effective value to the device addressed.

Each operator console has its own operator control system, which functions independently of the others. The topology of the operator control system is shown in Figure 285.

An operator intervention is generally distinguished from a design intervention. The plant operator operates while the design engineer designs. The distinction is that an operator control action always communicates with an instruction acceptor (as an existing entity). Design (configuration) functions define, delete, and manipulate all possible types of objects. Linguistic usage aside, the actions of the designer can also be understood as "operating." Design functions are initiated and, on the basis of the operator instructions, cause appropriate object manipulations to be performed.

Figure 285. Structure of the operator control system
OIN = operator input; OCO = operator control; IAC = instruction acceptor; DCC = display and control component; LOC = local component

The sequence of events in a typical operator action is as follows:

Selection. The operator action is generally initiated from an operator window, which provides the operator with all information needed for operation, such as the current value of the variable to be manipulated, local enabling of operator control, control limits to be maintained, or process states relevant for operation. The structure of the window and the information furnished in it are governed by monitoring functions. An operator window should be openable regardless of operator authorization. The variables that can be manipulated by the operator are indicated in the window (e.g., shading as in a pull-down menu system).

The first step in the actual operator action takes place when the operator selects a variable or variable group for manipulation. The operator control system checks whether the selected variable is manipulable and whether the operator is permitted to manipulate it. Several options are

available for the nature and syntax of the selection. It can be effected, for example, by entering a command on the keyboard, or by clicking on a symbol marking the variable. Once a selection has been made, the operator control system is in instruction mode. Now the operator can identify and manipulate one of the selected variables or can terminate the control action. In general, concurrent selections of an instruction acceptor are permitted. The instruction acceptor does not know whether it is selected or not in an operator control system. The instruction acceptor is not occupied by being selected. The same variable may be concurrently selected for manipulation in several operator control systems.

Input. The control value is input in a specified input syntax. A wide variety of possibilities exist, depending on the type of input device, the type of value, and the control philosophy employed. Some possibilities are as follows:

- Input the value on the keyboard and press ENTER
- Click on the appropriate symbol to change a binary value
- Simultaneously press the command key and the release key (two-hand operation)
- Press an UP or DOWN arrow key to increase or decrease an analog value
- Move a slider

All these actions ultimately constitute a control instruction in the operator control system. Once the input is complete, the instruction is sent directly to the instruction acceptor concerned.

Control Instruction. The operator control system transmits the control instruction to the instruction acceptor, which may be located in the same component as the operator control system or in another component of the system. If the operator control system does not succeed in properly transmitting the instruction to the instruction acceptor, the manipulation is considered not possible or rejected. If the instruction is properly transmitted to the instruction acceptor, the acceptor begins to process its methods. First it checks whether the manipulation is permitted from the standpoint of the application. During the processing of these acceptor methods, no other control instruction can be transmitted to the acceptor. Although such a collision is extremely unlikely, the process control OS must exclude this possibility.

Processing of Instruction Acceptor Methods. Data security in a process monitoring and control system requires that the instruction acceptor have its own methods, which it uses to check whether it will accept a control instruction or not. System solutions in which the effective value in the instruction acceptor is directly overwritten by a control action should be avoided.

In the context of the connector model, an instruction acceptor is an input connector of a write connection. The events at the instruction acceptor can be described as follows in this model: The connector consists of two parts, a system unit and an application unit. The control instruction is first received by the system unit, which checks whether the connector is enabled and whether the instruction is formally correct. The system unit then starts the application-specific method component of the instruction acceptor. In this section, customized for the application, a check is made to determine whether the specified value is or is not permitted on the basis of the instantaneous state of the application. If the value is acceptable, it is taken over as the new effective value; if not, the old effective value is retained. The execution of these steps is recorded in a message stating that a manipulation was attempted and whether it succeeded or failed.

Reaction on the Part of the Process. The operator control function described here is strictly limited to the transmission of the control instruction. The consequences of such an instruction have nothing to do with the control function itself. Once the control instruction has been entered in the instruction acceptor, the control action is terminated. The process consequences of the control instruction can be tracked by, for example, the monitoring system.

An important point for the operation of a process control system is that the operator always be notified of the acceptance or nonacceptance of a manipulation. A control instruction must therefore be processed and passed on to the instruction acceptor immediately after its input. Processing in the component that houses the acceptor must be interrupted so that the checking methods of the instruction acceptor can be processed. The total time between the end of input and the report from the acceptor must be no more than 2 s, or 4 s in the worst case.

In order to maintain this timing, many systems simply acknowledge the input directly

from the operator control system, only supplying it to the instruction acceptor later. Such solutions should always be rejected. They give the operator a false picture of the facts, and if difficulties arise, they result in a loss of confidence in the correctness of the status display.

Message Handling. "Messages", in general terms, are explicit reports on important events. Not every change of state in the system leads to a message.

Among the purposes served by messages are the following:

- To inform the plant operator about events in the process
- To provide the maintenance personnel with information about malfunctions and changes of operating status in the plant
- To furnish the production manager with key data on the production process
- To document the process in the plant

The following restrictions apply:

- Messages do not serve to replace records of status, switching logs, and detailed event reports needed for event analysis.
- The recipients of messages are always special message system units. Messages do not have the task of notifying other applications that an event has occurred so that automatic control processes can be initiated.
- The message functions do not update the state image in the display and control components during startup or operation.

The functional unit in which a message is generated is referred to as the "message source". The inclusion of a message source establishes that a certain event is so significant that a message is to be transmitted when it occurs. Two distinct concepts are employed: decentralized (distributed) and central message generation.

Decentralized Message Generation. In the decentralized message generation, the message sources are built into the lowermost functional level at which the significance of a signal can be determined. Message sources can be integrated directly into the process functional units. Examples include the following:

- Malfunction of a motor interlock: Interlock malfunctions are generally classified and reported as significant events. A malfunction of the interlock is detected in the motor control and can be reported directly from this unit. In other words, the functional unit "motor" acts automatically and independently to generate an appropriate message.
- Channel failure in a module: Channel failures are always reported as control hardware malfunctions. An intelligent module can independently generate a message if such a malfunction occurs.
- Arrival at a mark in a recipe sequence: When a significant mark is reached in a recipe operation (e.g., "preliminary reaction completed"), the recipe control unit can automatically generate an operational message.

Under a concept of this type, messages are created in all local functional units as well as in various modules and components. The messages must first be conveyed securely to the respective message receivers. In the distributed concept–and this is an important advantage–message transportation can be effected by system services.

Figure 286. Structure of the message system in a system with decentralized message generation
DCC = display and control component; LOC = local component; MAR = message archive; MEI = message interpretation; MRC = message receiver (central unit); MRX = message receiver (auxiliary unit); MS = message source; MTS = message transmission receiver

Figure 286 illustrates one configuration. Messages are always generated in message sources and locally delivered to a message transmission server. Each logical unit has its own local message transmission server. The task of this

device is to collect the messages from a component, hold them in interim (buffer) storage, and transmit them by secure means to designated message receiving and archiving units.

Centralized Message Generation. A concept based on centralized message generation is shown in Figure 287. Messages are generated exclusively in the central component, where message generation, message archiving, and archive interpretation are generally combined.

Figure 287. Structure of the message system in a system with centralized message generation
DCC = display and control component; LOC = local component; MAR = message archive; MEI = message interpretation; MG = message generation; MS = message source

The centralized concept is based on a different information model from the decentralized one. In the distributed concept, not all events must be reported to the central units via system communications. For example, a change of state of the control valve of a two-position controller is a normal operational event of secondary importance. This switching operation need not be reported and documented as an event. In the decentralized concept, reporting of the state (instantaneous valve position) for representation in an image is handled by services independent of message transmission.

The centralized concept links state and event reporting. The central component usually maintains a 100 % image of all required states for this purpose. When an event occurs in a central component, the state image is updated to reflect the state affected by the event. A check is run in parallel fashion to determine whether the event is one that must be reported. One problem in the centralized message concept is the management of information between multiple central stations. For every message, there must be no more than one message source in the entire system. The acknowledgement status is managed at this message source. Regardless of where it takes place, every acknowledgement must lead to resetting of the acknowledgement request, so that the acknowledgement is central for the entire system. In this respect, many control systems with centralized message generation (in particular SPC-based systems) do not have a clean structure. They do not support the sharing of message functions among central components and do not offer the possibility of central acknowledgement.

Content of a Message. The following information must be contained in a message:

- Who sent the message? Each message contains the identification of the message source and of the process unit in which the event being reported took place.
- When was the message sent? Every message contains a timestamp giving the time when the event reported took place.
- What was reported? Every message contains a precise description of its meaning. This description can be a plain text or a pointer to a plain text.
- How important is the message? Each message has a certain significance class, for example alarms, warnings, out of tolerance, sequential event report, and so forth.
- What change of state occurred? A message is sent whenever a change of state occurs in the message source. In general, a message contains the state in effect after the change and the nature of the change. Types of changes include, for example, “incoming”, “outgoing”, “pulse”, “acknowledged”, and so forth.

Along with the message source ID, the timestamp, the state, and the type of state change must be entered as instantaneous values at the moment when the message is created. Other information can be appended to the message later. The key here is the message source ID.

Message Transmission and Message Distribution. The task of the message transmission server is to receive, buffer, distribute, and transmit messages to the proper receiving and inter-

Figure 288. Sequential event display

pretation units (see Fig. 286). Message transmission servers must therefore insure that no message gets lost, even during a flurry of messages.

Message distribution can be described by the following general picture: The message receiving unit logs on to the message transmission servers every time a message is received.

There is one "main" message receiving unit. Other "secondary" message receiving units, for certain message groups, can log on to the message transmission servers in parallel. If the main message receiving unit fails, the message transmission server attempts to buffer messages until a replacement unit has logged on as the new main receiving unit.

Message Receiving and Archive Units. The task of a message receiving unit is to receive incoming messages and enter them in the logged-on archive. The most important archive is the sequential event archive.

All incoming messages are chronologically entered into the sequential event archive. Figure 288 shows a sequential event display, in this case an excerpt from the last messages entered in the archive. From the sequential event archive, messages can be grouped under a wide variety of criteria, for example sorted by charges, plant sections, significance classes, time intervals, and so forth, or by combinations of such criteria (see Fig. 65).

Besides the sequential event archive, there is usually a list containing all message sources that have generated current messages. Figure 289 illustrates such a list. A message source appears on this list (it is said to be "signaled") if either the event-generating bit is still set (value still out of range) or acknowledgement has not taken place yet.

Archiving. If processes are to be studied in retrospect, certain events and the time variations of certain states in the system must be archived. The resulting data can then be accessed by interpretive functions. The outcome of an interpretation can be output in the form of, for example, plots or lists. In modern systems, a strict distinction is observed between the data stored in the archive, the interpretive function per se, and the form and representation of the printout. While data storage in the archive is structured in keeping with considerations internal to the system, the user can define what the interpretive functions are to do and in what form the reports are to be output. Archiving presents a number of problems that can be solved only with the aid of special system services. Examples are:

Figure 289. List of message-originating sources

- To append on-line process data quickly and reliably
- To carry out informational functions in parallel with the continuous addition of new data
- To safeguard the data automatically
- To implement the archiving functions in redundant fashion (see Section 3.2.)

Time Synchronization. Time (clock) synchronization is an essential system function in a distributed process control system. If events are to be listed in time order, the messages must be timestamped as near as possible to their place of origin. This may be in a local component or may be in a module where, for example, a control hardware malfunction is detected. A sequence of two events in two distinct system units can be correctly detected only if the clocks in the two units "tell the same time". Synchronization insures that the time discrepancy over all clocks in the system will fall within a narrow time interval. A typical value is 10 ms; specially equipped systems achieve discrepancies of < 2 ms.

The time is absolutely specified by a central system clock. Additionally, radio clocks are employed as system clocks, with the advantage that time changes (e.g., from standard to daylight-saving time) are performed automatically.

Process Control Hardware Diagnostics. The diagnostic functions monitor the operation of the control hardware and include tools for analyzing the state of the monitoring and control equipment. System diagnostic functions fall into three groups.

The first group includes *control hardware monitoring functions*, which are integral constituents of the individual control system modules and functional units. These functions run automatically and continuously. The result of each check is written into the disturbance status of the unit concerned and can be read from there. If the trouble status of a unit changes, the unit automatically sends a hardware message. Hardware messages get special treatment in many systems, although this is not really necessary. That a message is a hardware message can easily be determined, either directly by examining the message source ID or indirectly by means of a special flag in the message. In this way, control system hardware messages can be treated in the same way as process messages. Typical hardware messages include:

- Failure of an I/O channel (alarm)
- Failure of a redundant bus connection (warning)

The second group takes in *diagnostic functions* of interest to the *designer* or to the on-site

technician. These have to do with special system analyses that are initiated by the operator only as needed. The functions are supported, in many cases, by external diagnostic equipment. Examples from this group are functions for analyzing the following (and comparable functions):

- The current configuration
- Memory utilization and processor load
- Run-time measurements

The third group consists of *diagnostic functions* used only by specialists at the *manufacturing firm* which permit detailed analysis of system behavior.

7.5. Design and Commissioning

Before a plant is operated, it must be designed and commissioned. The engineering work necessary for this purpose is a key item in the total cost of a process control system. The distribution of the work varies widely. In a decentralized process control system with a well-designed OS and the proper design and commissioning support, pure system procurement costs are relatively high but design and commissioning costs are low. In a "cheap" system (most SPC-based systems fall into this category), the hardware is favorably priced but design and commissioning costs are substantial.

The discussion in this section is based on the structural model of design and commissioning shown in Figure 290.

Design. The design process begins with the technological task statement. In practice, however, all that is usually available is a piping and instrumentation diagram. Informative documentation on the functional relationships is either nonexistent or, for the project team at least, difficult to access. Functional data are often found scattered throughout the process development reports or in descriptions provided by the equipment fitter. Accordingly, one of the most important tasks for the project team is first to gather together all such information, develop the functions, and describe them in a formalized way in the project specification (see Chaps. 2 and 10). This formal summary may well take into account the structure of the later implementation. For process control, this means that the specification takes the form of not a list of requirements, but a role system with certain functional properties. This role system can be refined stepwise and ultimately can be employed as the basis for the implementation. Thus the process control specification can be expanded later, thus becoming the documentation of the process control system.

An important advantage of this approach is the systematic procedure. Each function discussed in project conferences can be directly incorporated into the role system as a property. As a result, efficient design work with few errors is possible, and the operational aspect of the procedure is implementation-oriented.

In what follows, the design steps required in such a procedure are presented in detail in terms of the structural model of Figure 290.

Definition of Technological Module Types Required. The definition of a suitable collection of module types generally precedes the design work. Industry and corporate standards apply in many cases. The GMA is now working to define a standard set of module types, and the IEC has recently taken up this project.

The following criteria must be considered in establishing the module types:

Manageable functional scope.

Functional modules should be neither too small nor too large in terms of functional scope.

Small modules permit very flexible structuring of functionality and thus can be used very generally. The disadvantage is the large number of small modules and connections required, resulting in increased design and object management costs. The error rate increases, and the efficiency of processing falls off drastically when the system is later mapped onto the functional system. Another drawback is the low degree of functional standardization that inevitably results from the element types defined.

Large modules permit fairly standardized structuring with a few modules. Large modules can be efficiently processed in the later mapping in the functional system. The disadvantages of large modules are the cost of defining them, their functional rigidity, and the possibility of an excessively broad spectrum of models. If large modules are to be used, a consensus must be found as to their functionality. Because these modules embody technological standards, this is a much costlier operation than for generic small modules. To cover all technological cases,

Figure 290. Structural model of system design and commissioning

either the modules must be made very extensive, with many selectable and parametrizable options, or a great number of types must be defined for fairly similar technological tasks.(What functions must a motor control module contain, and how many distinct motor control modules are desirable?)

Feasibility of using functional module types. It makes little sense to define technological module types such that their later mapping onto functional module types is difficult or impossible. It is therefore essential to check, while fixing the technological module types, how they can be realized in various systems.

Configuration of the Technological Role System. From the spectrum of types, the required

modules are identified, instantiated, connected, and parametrized. The result is a technological role system in modular form. In accordance with a structure such as the hierarchical structure of Section 4.5, this role system is broken down into individual function, group function, plant coordination, action, and other levels. This technological role system comprehensively and formally reflects all requirements derived from the technological task statement.

The documentation of the technological role system can be regarded as a formalized specification. In addition, it directly serves as the basic documentation for further design work specific to the process control system. The technological role system itself should be formulated in a manner largely independent of the control system (see also Chaps. 2 and 10).

Definition of Functional Module Types. Along with the firmware or special-purpose software, most manufacturers of process control systems supply a collection of functional module types. If the user remains with these prefabricated types, the complicated procedure of creating customer software module types can often be dispensed with. Indeed, many process control systems do not allow user programming of software modules.

Thus it is chiefly the manufacturer that defines the functional module types. The user must manage with these manufacturer-specific collections of types. Only in special cases can a competent user define and program new sets of types; such a user will attempt whenever possible to create software module types that exhibit a 1:1 correspondence with the functionalities of the technological module types used. Otherwise, the manufacturer must attempt to satisfy user requirements.

Configuration of the Functional Role System. The functions embodied in the technological role system are transformed into software structures specific to the control system. In this process, the structures of the technological role system are preserved in unchanged form as far as possible. A frequently used aid is the creation of"typicals."

Typicals are pre-assembled structures made up of functional module types. They are not types but structures having special naming conventions and which can be easily copied in the design interface. Typicals can readily be put together by the user. If typicals are created that functionally correspond to the technological module types, the functional role system can easily be configured with the aid of these typicals.

The configuration of the functional role system falls into two parts:

- Mapping the technological structure onto the functional structure specific to the control system
- Establishing the locations of individual functional units

"Location" here refers to the logical location of a unit. For a module, for example, this is the logical card slot; for a software module, it is the processor board in which the module is run.

Once the network of software modules has been defined, it is therefore necessary to establish which modules will be run on which processor boards. The component and module structure of the process monitoring and control system must be known, at least in outline, before this step can be done.

The result is the finally configured functional system. In a design system, functional units are handled as objects; they can be represented and documented in accordance with certain criteria and be loaded directly into the functional unit for execution.

Commissioning (see also Sections 10.5 and 10.6). Commissioning includes all actions required to bring a system or system unit from an initial state to an active working state. A single functional unit, a group of functional units, a whole system component, or a complete system can be commissioned. In defining what will be regarded as the initial state, one commonly takes an organizational (management) view, defining the initial state to be whatever state the commissioner finds when the operation begins. In a process control system, for example, the initial state is the system fully installed but not yet energized. When a compact device is purchased, commissioning starts with unpacking. Certain simple installation tasks may thus be included in commissioning.

From a systems engineering standpoint, commissioning is the last step involved in making the functional system available for service. The functional system includes all subsystems

Figure 291. Availability states of a functional unit

needed for active implementation of production operation.

Availability of a Functional Unit. The functional system is the system that actively realizes production operation. Its units fulfill roles whose interplay results in the desired system functionality.

The separation of role systems and functional systems is of central importance for an understanding of commissioning.

A functional role system is set up in such a way that for every role there is a functional unit that plays this role. For a functional unit to carry out a role, it must be allocated to this role and must be made available at the defined location of the role. This part of the operation is called "installation".

Figure 291 illustrates the availability states of a functional unit along with the transitions between these states.

- Not present: There is no suitable functional unit at the location. For example, the card is not plugged in or the software module is not loaded.
- Install: Installation means making a functional unit available; for example, assembling a cabinet rack, plugging in a card, or loading a software module. There are two key events in installation: when the functional unit is physically present at the location, and when the functional unit has been configured for the task it is to perform. The order of these events is not significant here and can be determined case by case. For example, in installing a card, the jumpers are placed first and the card is then plugged in, whereas for installing a software module entity, the entity is created first and only then are values assigned for the parameters.
- Present: The functional unit is said to be present after installation; i.e., it is finally configured for its role and is available at the location designated for the role.
- Make ready: The state of the object after installation, for example of a newly loaded software module, is generally undefined. A special function called "make ready" must be carried out in order to bring the object to a well-defined "ready" state adapted to the instantaneous system state.
- Ready: The availability state "ready" means that the unit is not only present but also ready to start. In other words, at this instant all conditions exist for connecting the unit actively into the network. The "ready" state plays an important role specifically in distributed process control systems. Here the situation often arises where certain units have already been activated and begun carrying out their tasks. A further unit is now to be connected into this running structure. Naturally, such a connection must not be made except under certain conditions. The "ready" state indicates that these synchronization conditions exist at this moment and the unit can be connected into active operation.
- Start: From the "ready" state, a functional unit can be started. It then goes into the "operating" state.
- Operating: In this state, the unit is effective in the functional system as an active element. It is performing the role intended for it.

A typical situation in a distributed process control system is where the functional systems are operating in certain regions and not in others (see Fig. 292). The process control system is purposely designed so that functional units can be handled in a "granular" fashion. If a functional unit is not operating, no role that is performed by this unit can be realized. In the example shown, modules C and E are not operating; modules A, B, D, and F are operating. To the extent allowed by disrupted communications relations I, II, III, and IV, the operating modules are fulfilling the role intended for them.

Figure 292. Functional system with several unavailable units

Hierarchy of the Functional System. The functional system of a control system should be regarded as having a multilevel structure. Each level satisfies the role requirements of the next higher level.

The structuring and implementation of a functional system are always carried from the bottom up, starting from the physical hardware units. This strict bottom-up principle underlies all commissioning and startup operations.

Figure 293 illustrates a typical functional system structure for control system hardware. Each functional unit can operate only when all functional units are operating in the lower levels on which it is built. If a functional unit fails, no functional unit in any higher level that requires the failed unit for the execution of its role will remain in the "operating" availability state.

- Hardware level: The hardware level furnishes devices, modules, displays, cables, and so forth as functional units. The lowest level of an industrial functional system is always the physical level. Without a physical basis, no industrial functional system can operate.
- Base system level: The base system level provides the base operating system, the required databases, and other standard tools (e.g., standard communications tools) as functional units. The control system functions are built up as actively available units from these standard tools.
- Process control level: The process control operating system level includes all functional units needed for the management and executive control of technological functional units. Examples from this class are system functions such as module processing, module-to-module communications, message generation, operator control, display, archiving, and so forth.

Figure 293. Hierarchical structure of the functional system

– Application level: The application level implements the process control functions on the basis of a functioning process control operating system. If process control is structured in a hierarchical fashion, the application level itself can be regarded as a hierarchical system of process control functions, one built on another. Commissioning of the process control system based on operating software modules is a special aspect that will not be discussed here. From the standpoint of the process monitoring and control hardware, the application level consists of a flat network of intercommunicating modules.

8. The Process Control System and Its Elements: Information Logistics

8.1. Principles

The need for information integration in production companies is generally acknowledged today, but this effort is subject to two kinds of limitations. The first are due to historical circumstances surrounding the introduction of computer-aided information processing ("island" solutions); the second have to do with the heterogeneity of the computer systems employed, which in turn stemmed from functional requirements. The starting point for solving the associated problems is the derivation of the requisite integration functions along with their scope; the process is aided by proper interface definitions and standards. Two worlds are involved here: the world of production engineering in the definition of what functions are needed, and the world of information and data processing in the implementation of these functions. Informatics is called on to create suitable methods and tools for the second range of problems. All experience to date shows that optimal solutions demand close cooperation between the two fields; this necessity represents a special challenge because of, among other factors, difficulties in understanding functional requirements and differences in terminology.

The new field of "information logistics" will contribute to an integrated view of methods and tools for information distribution and processing in production plants. By analogy with the logistics of materials, energy, or personnel, information logistics combines methods that are concerned with the modeling, distribution, storage, and retrieval of information. The new field must identify the interrelationships of these individual disciplines with regard to the tasks of information processing in production and, with the aid of tools, must put them to work in optimizing information-logistic systems. The methodological edifice of information logistics is not yet complete [591, 592], but separate disciplines do already exist in distinct form. One such is distribution – the "communication" of information within the company – which is treated in depth in this chapter.

8.2. Functional Structures and Information Flow in Production Companies

For a better understanding of what requirements manufacturing information systems must meet [593, 594], it is desirable to work out models of information flow in the company. If such information flows in production companies are examined more closely, an information hierarchy such as the one shown in Figure 294 is revealed [595]. The subdivision of production companies into various control and management levels arises from the way corporations are organized, and so the details will differ from one industry to another [596]. A consistent feature, however, is that the lowest level of the structure includes many single items of information about processes, while this information is more and more strongly condensed in the higher levels (all the way up to corporate management). Conversely, the objectives of the higher levels of management and control give rise to items of information about production steps or stages at the lower levels. Figure 294 shows that these processes can extend to various levels and take a variety of forms. Again, structural differences between industries and companies are a factor.

The subdivision into corporate, plant, and process levels (Fig. 294) is specific to the process industries, because here it is often the case that independent facilities on the process control level are supplied with production specifications (e.g., recipes) directly from the production

Figure 294. Levels of control in production

management level. In other industries, such as iron and steel, the products move in sequence through a number of plants or units where the raw material is upgraded, step by step, and ultimately converted to a salable product. This production structure is advantageously described by introducing an extra or intermediate level of management or control. This intermediate level breaks the general instructions from the production management level down into detailed instructions for the individual production units.

This structure implies that information flows both vertically (between control levels) and horizontally (within each control level). Both the transport and the storage of information reflect these information streams. Information logistics has to supply methods for the modeling and optimization of communications and information storage systems.

In general, the various levels employ disparate computer systems for information storage and processing. Information logistics, however, demands suitable high-capacity information pathways within and between the levels of control. It should be pointed out that information logistics is not just one of the tasks involved in information integration for production companies; it is a methodological aid to the planning and implementation of a corporate information utilization policy. Data communications and storage facilities do not become information communications and storage facilities until the meaning and utilization of the (digital) data have been established.

At first, information integration across the control levels of Figure 294 was thought of chiefly as a problem in manufacturing engineering. One indication of this is the wide adoption of the term CIM (computer-integrated manufacturing). Nevertheless, process engineering requires the same kind of information integration and has a functional structure wholly congruent with Figure 294. The term CIP (computer-integrated processing) is seen more and more often in this connection, showing that information integration is increasingly regarded as vital in both branches of production. It is therefore suggested that CIP be taken to mean computer-integrated production; this term expresses the fact that the same methodological aids will be applicable, and must be available, for information integration in all kinds of production operations. An analysis of the steps involved in manufacturing further shows that there are not only the discrete, piece-by-piece operations but also completely continuous "process-like" operations. If information integration becomes a way for methods of manufacturing engineering and process engineering to come together, this will be in accord with the situation in the plant. The integrative techniques of information logistics can then be put to optimal use.

8.3. Computer Communications Between and Within Control Levels

The need for information communication between the levels of Figure 294, as well as the

Figure 295. Networks for computer integration

requirements of information logistics, demand that appropriate aids be made available in the production company. As Figure 295 shows, the implementation of computer-aided information communication calls for a hierarchy of computer networks [595]. The information-handling facilities at each level of control must meet the following two requirements:

- There must be dedicated computers at each level. Information processing for more than one level can be combined in one computer, but the unavoidable increase in system complexity will result in a loss of flexibility, efficiency, and maintainability.
- The communications facilities at each level must be tailored to the particular needs of the level. The communications equipment

must also be able to connect heterogeneous computer systems together when a level uses computers of different generations, types, and capabilities because of special requirements, procurement strategies, or historical circumstances.

The networking concept illustrated in Figure 295 is one approach to meeting these demands. The following points may be important in individual cases:

The communications facilities must be designed and implemented with attention to the necessary time and consistency conditions. The effort of determining and modeling such conditions is justified by the optimal economics and flexibility of the communications system.

The communications system must be fault-tolerant as well as safe and secure with respect to intentional and inadvertent falsification of information. The redundancy and coding procedures employed for this purpose should be selected to fit each application [597].

Because production facilities are continually being changed, information logistics must be correspondingly flexible. Well-defined and, when possible, standardized interfaces and communications rules (protocols) are needed in order to meet this requirement economically, especially in heterogeneous systems.

Information integration across all levels of management and control is possible only if all information is in digital form.

However, information integration does not mean just data communications between one computer and another. Information logistics, in particular the transport and storage of digital data, must be supplemented by conventions on the meaning (semantics) of the digital data. The producer and consumer, who may be in different areas of activity, must interpret the digital data in the same way; only then do the data become information. Thus, when disparate computer systems are formed into an information network, it is particularly important that protocols be defined and standardized for semantic transition areas between applications systems. Formal methods of syntactical and semantic notation, based on experience and results from informatics, should be fully utilized for this purpose.

8.4. Computer Communications in Industrial Production; Standards

Standards already exist for the implementation of computer networks. These are discussed from a technical standpoint in what follows. The equally important economic aspects of various approaches call for an exact knowledge of each situation and its constraints. Computer-integrated production does not exist as an off-the-shelf solution, but the existence of standard protocols, however, makes it easier to handle specific applications problems.

Communications at the Process Control Level. Plant computers and the technical process often communicate (Fig. 295) through intelligent subsystems, for example stored-program control systems (SPS) or field-level multiplexers (MUX). Other direct methods of communication include digital input/digital output (DIDO) and standard serial and parallel buses (SCSI, IEEE 488, RS 232/422/485). Field buses, which permit serial data transfer under field conditions, are especially important and are treated in depth in Section 8.6.

Local Area Networks (LANs) at Higher Control Levels. Local networks have become vital in connecting computers with near real-time functions, such as plant unit, plant, and control-room computers, at the process and plant control levels. These setups allow both protected communication between two partners and unprotected simultaneous communication with more than one partner in the network (broadcasting). Physically, these networks are available based on either copper wire or optical fiber. The standard for levels 1 and 2 is IEEE 802, which has now been adopted by ISO as well. Line access protocols are CSMA/CD and token-passing. The CSMA/CD protocol (ISO IS 8802/3) has found wide acceptance in office systems, and a number of industrial products are on the market. This protocol is easy to implement, but the possibility of collisions means that transmission times are not well-defined. Its applicability under real-time conditions is therefore controversial.

In the token-ring protocol (ISO IS 8802/4), permission to transmit is linked with possession

of the "token," a special data structure sent in the form of a telegram. There is no possibility of colliding transmissions. Certain participants can be assigned priorities for permission to transmit through special token distribution mechanisms, so that even worst-case communications times are guaranteed. As a result, the token-ring protocol is particularly suitable for real-time applications. On the other hand, special fault-tolerance methods should be noted, such as the replacement of a lost token, which can markedly increase the administrative effort involved in running the token protocol compared with the CSMA/CD protocol.

Open Networks (WAN = Wide Area Networks). At the production and corporate levels of control, computers must communicate over distances longer than the few kilometers to which local area networks are restricted. Wide area networks (WAN) can link two communications partners over any distance, worldwide. In contrast to the broadcast mode of LANs, connections between nodes in open networks must be explicitly opened and closed. A variety of transmission media are available: all kinds of copper wires, wireless links (radio, satellite, infrared), and optical fibers. Open networks are characterized by the possibility of adding new participants while the network is in operation; therefore, communications standards are especially important in this area. ISO is making its contribution in the well-known OSI model [598]. Both LANs and WANs can be employed at all levels shown in Figure 294; special applications requirements may make the use of an open network desirable even at the process level of control.

Communication through Private Branch Exchanges (PBXs). The private branch exchange (PBX) has been a common installation in all kinds of companies for decades. For computer communications, the PBX has many of the properties of an open network [599]; for example, it sets up a point-to-point connection between two participants. A point to consider is the nonnegligible, and unpredictable, time needed to establish and drop connections, which are thus only partially suitable for real-time applications.

An important development is the transmission of digital data in parallel with telephone traffic, which is still partly analog but will be increasingly digital in future. With equipment now on the market, the Integrated Services Digital Network (ISDN) is limited to 64 kbit/s for the transmission of digital data. The PBX is therefore more suited to the transmission of digital data in parallel with speech at present, and isthus interesting chiefly at the corporate and production levels of control. The introduction of faster call-processing devices (with processing times in the millisecond range) will allow the PBX to penetrate local area network applications in the medium term.

8.5. MAP/TOP: Protocol Standards for Information Integration in Production Companies

Experience with the ISO standard protocols for data communications between computers [599] has shown that the standards are not adequate for true information communications. Up to the beginning of the 1980s, level 7 of the OSI model (the applications level) included only fairly general functions (file transfer, virtual terminal, etc.) with no reference to the meaning (semantics) of the transferred data. What was defined was thus tools with which the user could construct an information integration.

While this was a significant advance for computer communications applications, with their initially commercial orientation, the broad functionality and thus the semantic variety of the digital information that must be handled when computers are integrated into production meant that further standardization was needed on level 7 of the OSI model (see Fig. 296). This situation has led, since 1980, to proposals for MAP (Manufacturing Automation Protocols [600]) and TOP (Technical and Office Protocols). These proposals originated with users of automation and process control systems. MAP was developed by General Motors for purposes of manufacturing automation and, TOP, by Boeing as an approach to automating the engineering office.

MAP and TOP together provide for comprehensive information communications in industrial companies, from the administrative and resource allocation aspect through design and development (CAD) to computer-aided produc-

Figure 296. MAP/TOP protocol hierarchy

tion and quality control (CAQ). Both protocol environments constitute a key tool for CIP (Computer-Integrated Production).

The impetus for MAP and TOP came from users of industrial automation and process control systems. It is in the user's interest to select from the widest possible range of options the optimal solution to each problem while insuring the integrability of the new features. This is the alternative to the "single-source" solution often put together by one computer manufacturer. The interests of the suppliers and users of automation and process control systems are in conflict here: Complete standardization of interfaces for a wide variety of information-processing devices in a production company will breach the protective walls around computer networks, which have commonly been supplied by one vendor. On the other hand, this standardization trend expands the market for each vendor. The prerequisites are precise and strictly consistent standardization of protocols and a user with sufficient know-how and capacity to cope with the interoperability problems.

Objectives and States of MAP/TOP. The full definition and application of the MAP/TOP protocol hierarchy should guarantee direct communication between computers, control units, and their programming systems, even when these are supplied by different manufacturers. The objectives of MAP/TOP take in the following points:

The protocols should allow for the special properties and requirements of local plant and office networks. Further, they should be as compatible as possible with the respective open network protocols, so that communications between the two types of networks can be simplified (Fig. 295).

In contrast to the ISO protocols for open networks, with the few generally applicable functions of applications level 7, the MAP/TOP protocol hierarchy for level 7 includes special applications functions tailored for manufacturing and office automation (e.g., MMS = Manufacturing Message Specification and MHS = Message Handling Specification).

Figure 297. Application-oriented Companion Standards

In support of these ambitious objectives, the MAP/TOP definition includes quality-assurance measures such as conformity tests, which insure and certify the ability of protocol products from different manufacturers to communicate with one another.

Thus the objectives of MAP/TOP go beyond those of the ISO open network protocols, taking on the difficult task of identifying and standardizing applications functions in the manufacturing and office area at level 7. This makes it clear why the development of MAP/TOP, especially the applications protocols, is still in flux and will not be completed in the foreseeable future.

Figure 296 illustrates the MAP protocol environment as now available. At levels 1 and 2, the LAN protocols discussed in Section 8.3 are standardized. Levels 2 to 6 contain protocol definitions equivalent to WAN protocols (the same for MAP and TOP). The use of these protocol standards at levels 1 to 6 insures data communications between applications functions in production and office.

On applications level 7, three protocol types are distinguished. The first corresponds to the ISO protocols for WANs; these are essentially ISO standard applications protocols such as file transfer.

The second protocol type covers application-specific functions. Examples are the MMS protocol family in MAP and the MHS protocol system in TOP (Fig. 296). A third protocol type on level 7 deals with the functions of network administration; examples are Network Management (NM) and Directory Service (DS). These protocols also offer functions for handling errors as well as fault-tolerance practices.

Figure 296 shows the intention of the ESPRIT CNMA (Communication Network for Manufacturing Applications) project, a European undertaking that supports MAP and TOP in a similar way [601].

While the MAP specification focuses on manufacturing operations, a similar problem is evident in process operations. Proposals for a PMS (Processing Message Service) are therefore coming from a variety of sources. Its functions will correspond to the communications requirements of computers in the processing industries.

Generally, there is the problem of linking various functional environments to the basic MMS standard. Figure 297 shows the "Companion

Standards" concept that has now been chosen. A standardized MMS core includes generally usable concepts and structural specifications for applications standards that will serve as the basis for a variety of Companion Standards relating to technical specialties. This procedure allows the step-by-step construction and expansion of the applications function standards on the basis of user experience.

8.6. Field Bus Systems

Basis and Objectives of Field Bus Systems. Communication at the field level links field devices with control-level computers. The devices in question include sensor systems that locally acquire complex information about the production process; actuator systems that influence material and energy flows; and programmable (stored-program) controllers that perform local control and optimization tasks. The same holds, with suitable adaptations, for both processing and manufacturing operations.

Distribution, as a basic property of present-day control and instrumentation, extends to information processing at the field level and, to an increasing degree, blurs the distinction between sensors and actuators, on the one hand, and control computers on the other. This means that powerful communications systems meeting a variety of requirements are also needed at the field level. Examples include direct communication between intelligent sensors and actuators in local control loops, as well as communications links used to transmit product data between plant control systems and control computers.

Most signal transmission at the field level is by field devices individually wired to the control computers. The standard 0 – 20 mA and 4 – 20 mA signals are dominant in process engineering and have become standards in chemical engineering. In manufacturing, sensors and actuators on machines are also singly and directly linked to the cell computer or to programmable controllers.

The variety of information involved in modern production processes sets limits to this form of communication with regard to plannability, maintainability, immunity to electromagnetic interference, and economy. Field bus systems should overcome these limitations:

- The star configuration of individual lines is replaced by a digital bus known as the field bus. It is cabled to the various field devices and transmits digitized data via digital interfaces.
- Such a bus connects some tens of field devices among themselves and to a plant computer. If the devices are close together, the cost of cabling is substantially less than for individual cabling (Fig. 298). If field devices are assumed to be evenly distributed over a specified area, the savings in cabling costs can be estimated from Figure 299.
- The growing intelligence of field devices calls for the transmission not only of process measurements and control information but also of digital status and control data between field devices and control computers. The additional cabling that used to be required for this purpose can be omitted when the field bus is employed.
- The conversion of analog signals to digital locally, that is, at the connection to the field bus, prevents interference to the signal on route to the control computer. The redundancy of digital codes also makes it possible to reconstruct erroneous data.
- The standardization of field bus protocols permits standard information interfaces between field devices and a wide variety of control computers, so that open communication results at the field level. This is not possible at present with the wide range of information transmission media at the field level (Fig. 299).
- Diverse media can be used for digital data transmission (e.g., copper twisted pair, coaxial cable, optical fiber, radio waves), so that economic and technical optimization is possible (transmission rate, noise immunity, energy expenditure/intrinsic safety, electrical isolation, etc.).

These objectives and potential features make up the basis for field bus standards now being devised. The many degrees of freedom in the specification and implementation of field buses lead to a variety of approaches and have worked against the desired uniformity in field-level information interfaces.

Field Bus Systems in Development. Teams in several countries have made a start toward

Figure 298. Transformation from star-configured individual cabling to field bus structures

specifying and implementing field bus systems. The properties of an architecture for all these projects is described first. The various approaches to implementing this architecture employed in the several projects are then discussed.

General Field Bus Architecture. A field bus system is a local network having a restricted number of nodes, which communicate exclusively among themselves or with a control computer. There is accordingly no need for the services of ISO levels 3 to 5. Presentation level services are also unnecessary in general form, since they can be performed in special form by the services of level 7 or 2. For open commu-

Figure 299. Estimation of cabling costs in field bus structures [615]

nication between field bus nodes, however, the services of level 7 must be specified. A general field bus architecture thus includes ISO levels 1 (physical layer), 2 (link layer), and 7 (application layer). This reduced architecture must be supplemented by network management services as well as application-specific services on level 7, such as those already introduced as Companion Standards [602] in MAP/TOP.

The American standards group ISA SP 50 has defined two performance classes (H1 and H2) for the *physical layer.* The scope of H1 is the replacement of existing analog standard interfaces (0 – 20 mA and 4 – 20 mA); the H1 specification must permit adequately fast and error-proof transmission of process, measurement, and control signals. Accordingly, the H1 specification is largely governed by process engineering requirements.

The H2 specification is to extend the H1 concept to applications with higher performance demand. This includes the fast transmission of large data sets, as is needed for the loading of machining programs in manufacturing engineering. H2 is therefore specified for manufacturing. IEC TC65C has created specifications for a field bus standard for use in industrial control and instrumentation. In addition to the physical layer performance classes already cited, it describes other properties: the topology (linear bus or tree), the transmission medium (twisted pair or, later, optical fiber or radio link), and finally the number of nodes on each field bus segment (32). For performance class H1, a data rate of 31.25 kbit/s and a maximum cable length of 1900 m are set forth. Performance class H2 has a data rate of 1 Mbit/s and cable lengths of up to 750 m. The intrinsic safety of the physical layer

is handled by limiting the electric power that can be carried on the bus. The H1 specification allows enough power to run at least five field devices, at least three of which can operate in a hazardous environment.

The H2 specification provides for at least three field devices to be supplied on the bus and permits AC transmission over the bus lines. Intrinsic safety is not explicitly considered in the H2 specification, since it is of no importance as a property of manufacturing systems. At present, power supply to field devices, even with auxiliary energy sources, is not a function of field bus systems; over the long term, however, separating the information channel from the (auxiliary) energy channel in process operations is a goal to be sought [603].

The specification of the *link layer* in field bus designs corresponds to the ISO/OSI Data Link Layer (DLL). In this way, the two sublayers LLC (Logic Link Control) and MAC (Medium Access Control) are established.

For the application area of field bus systems in general, the *link layer* must provide adequate efficiency (real-time environment) and also support access priorities as well as point-to-point connection or simultaneous connection of one node with several or all other nodes (multicast, broadcast). The essential novelty of the field bus concept as described, however, lies in the procedures by which nodes access the common data transmission medium (MAC). While the French FIP proposal [604] features a centrally organized mechanism in the sense of bus allocation, other proposals (PROFIBUS [605]) utilize a distributed access mechanism based on token passing as set forth in IEEE 802.4. These differences exist because FIP assumes better real-time properties for the central bus control. PROFIBUS uses standard microelectronics for the efficient performance of the more complex token-passing protocol, which allows more flexible parametrizing of the bus allocation for individual nodes [606].

The *application layer* must furnish application functions without regard to the protocols of the lower layers. These functions must insure the exchange of information in a distributed system and with adequate efficiency. Because applications in industry, whether processing or manufacturing, are subject to strong timing conditions, efficiency is particularly important. This holds for cyclic information transmission as well as the detection of spontaneous events. While the functionality of the protocol services on the application layer can be specified independently of the lower protocol layers, their performance under real-time conditions is crucially dependent on the efficiency of all protocol layers.

The application layer for field bus systems must offer cyclic and noncyclic services. Cyclic services are, for example, the reading and writing of process variables or parameters as well as access to information on the validity and consistency of such variables. Noncyclic services include the sending of reports based on an event, the sending of management information, and the initialization or configuration of subsystems during startup of technical processes.

A variety of approaches can be taken to the implementation of such services. The essential difference lies in the relationship between the information-generating and information-consuming processes. For example, client/server models as well as producer/consumer models can be used [607]. Requirements on the field bus for applications in process engineering have been thoroughly described by Pfleger [608] and Drathen [609].

Already in MAP and TOP it was seen that the specification of complete function sets for all conceivable applications in industrial production is not possible in a uniform standard. On the basis of an MMS core standard (Manufacturing Message Specification, ISO IS 9506), special function sets have therefore been standardized for various application areas; these are called *companion standards* [602]. A similar procedure is also provided for the standardization of field bus systems. Companion standards define function blocks, such as those for the control of processes (analog and digital input/output, PID controllers, etc.) or for the utilization of production facilities (configuration, object description, maintenance, startup, etc.). The companion standards for field bus systems will resemble those for MAP wherever appropriate in terms of functionality. Büsing has described the importance of MAP for process control engineering [610].

In the ISO/OSI model, the *network management* functions supplement the transmission protocol functions and communicate with them. As in any case where intelligent subsystems

are networked, network management is also required for a field bus system.

Of the five management areas of the ISO/OSI model, the following are pertinent to field bus systems:

- Performance management
- Configuration management
- Fault management

The management functions for a field bus system are implemented in a network management station. Its functions and services include system initialization, the loading of programs and parameters, the starting and stopping of the communications system, the detection and localization of faults, and the reconfiguration of the field bus system in reaction to faults identified. Furthermore, the management station monitors the performance and loading of individual communications channels, identifies bottlenecks, and generates planning data for network upgrading. Such a network management component appears in all the field bus system now in development.

Incorporation of Field Bus Systems into the Information Hierarchy. As shown in Figures 298 and 299, field bus systems connect intelligent field devices with one another and with plant computers. They must support information transport at the field level but are also incorporated, through the plant computers, into the overall information pyramid. Since field bus systems are used in both processing and manufacturing, their real-time performance and message formats are subject to a variety of requirements.

Within the field level, real-time requirements are critical when information transmission over a field bus is within a control loop. Depending on the type of process being controlled, guaranteed transmission times in the range of a few milliseconds are needed; the messages to be transmitted are, however, short. The situation is similar for field bus systems in manufacturing cells. Longer messages and less critical real-time conditions occur when information is exchanged between CAD/CAM systems and manufacturing cells. The guaranteeable response time over a field bus depends on the types of services implemented.

When field bus systems are integrated into the information pyramid, it must be kept in mind that levels 3 to 6 do not exist or are emulated only to the extent necessary for direct field bus operation. This means that a special field bus node must offer the necessary network functions and also must have the requisite information about the communications partners at higher levels of the information pyramid. As in reduced MAP architectures, there must be a gateway that, on the one hand, is fully networkable and, on the other, can execute the field bus protocols (Fig. 300).

Constraints Arising from Applications. The ESPRIT CNMA project (Communication Network for Manufacturing Applications) carried out a survey to find out what operational constraints would apply to a field bus standard in the fields of processing and manufacturing engineering:

Processing:
Field devices to be connected:
Programmable controllers, sensor and actuator systems, minicomputers, field multiplexers, and power supplies for simple sensors and actuators
Information to be transmitted:
Cyclic (length ≤ 4 bytes, transmission time between 100 ms and 2 s)
Alarms (length ≤ 2 bytes, transmission in a few ms)
Overall field bus transmission rate > 250 kbit/s
Process dimensions:
Tens of meters up to roughly 2 km; distance to control room between 50 m and 3 km; total bus cable length between 75 m and 10 km
Ambient conditions:
High temperatures ($> 80\,^{\circ}$C), humidity, dust, vibration, electromagnetic interference; the transmission medium must be resistant to oil, steam, and ultraviolet; insulation must not contain halogens
Safety:
Intrinsic safety is an essential property; safety classes IP 65, NEC Class 1 Division 2
Conformance to protocol specifications
Certification of conformance in order to insure connectability, interoperability, and interchangeability of field devices on the field bus is regarded as important

Manufacturing:
Field devices to be connected:
Programmable controllers, numerical controllers, robot controllers; intelligent sensor and actuator systems are of minor importance
Information:

Figure 300. Linking of field bus and MAP LAN

Cyclic data (length 1 – 64 bytes, transmission time between 10 ms and 1 min)
Alarms (length 2 – 8 bytes, response time ca. 1 s)
Production data (length 2 – 256 bytes, time interval between 10 s and 8 h)
Process dimensions:
The diameter of manufacturing applications is ca. 10 – 80 m; usually the control room is nearby; bus cable length between 5 m and 50 m
Ambient conditions:
Severe electromagnetic interference, wide fluctuations in power supply voltage, static discharges
Safety:
No special requirements on safety or intrinsic safety of bus system
Protocol conformance:
Certification of field bus products for conformance to protocol is regarded as important

These survey results are reflected in different ways in existing field bus standards and those in preparation. The discussion that follows will deal with the most important properties of two field bus definitions. As early as 1989, Polke pointed out the needed separation into energy and information channels and questioned the requirement of "intrinsic safety" against the background of modern sensor and actuator systems [603].

PROFIBUS (Process Field Bus). PROFIBUS is a joint industry/science project in Germany, supported by the Federal Ministry of Research and Technology (BMFT), which prepared a field bus definition that is now a German standard (DIN 19 245). The PROFIBUS user organization (PNO) is charged to maintain and further develop the PROFIBUS standard.

PROFIBUS corresponds to the architectural principles discussed above and was conceived for use in both process and manufacturing industries. Its essential properties include the use of the token-passing access procedure on layer 2 and the Field Bus Message Specification (FMS) including network management over all layers. FMS [611] is derived from ISO IS 9506 (MMS = Manufacturing Message Specification) so that it can communicate with MAP applications in a simple manner and make use of experience gained in the development of MMS. A Lower Layer Interface (level 7 a) replaces the functions of ISO layers 3 – 6 needed for field bus

systems. A conformity test is included in the PROFIBUS definition.

At the physical layer, PROFIBUS defines a twisted pair cable with a maximum length of 1200 m (without repeaters) or 4800 m (with repeaters). If repeaters are used, the bus topology can be straight bus, tree, or star. The transmission rate can be between 9.6 and 500 kbit/s. The number of nodes can be up to 122, of which a maximum of 32 can be master stations. Redundancy, intrinsic safety, and transmission of auxiliary energy comply with the specifications of ISA SP 50.

Layer 2 of PROFIBUS (MAC) includes two protocols, the distributed token-passing protocol (IEEE 802.4 or IEC IS 88 204) and the centralized access protocol. In this way, communication among a number of master stations, or between one or more master stations and the substations (slave stations), is possible.

A special characteristic of the PROFIBUS definition is the use of standard processors for the protocol implementation, with a crucial effect on the efficiency of data transmission. On the basis of this efficiency, PROFIBUS at present is only conditionally suitable for service as a signal path between closed control loops with critical real-time conditions.

FIP (Factory Instrumentation Protocol). The FIP protocol definition has been in preparation since 1985, with support from the French ministry of higher education and research ministry. Its purpose is information transmission in a manufacturing setting. The FIP bus consortium includes more than 70 companies located in several European countries. There are at present three French standards for layers 1, 2, and 7. Other French standards for network management, MAP/MMS-compatible functions at layer 7, and optical fibers on the physical layer are in preparation [604].

The physical level allows for a maximum of 256 nodes. Three transmission rates are provided on the twisted-pair cable (31.25 kbit/s, 1 Mbit/s, 2.5 Mbit/s). The cable can be up to 3 km long at 1 Mbit/s. For optical fiber systems, the maximum length between two node connections is 1600 m (glass fiber) or 125 m (plastic fiber).

On layer 2, there is a centralized access control procedure (MAC), which supports both cyclic data transfer and the transmission of aperiodic data or longer messages.

The FIP definition, based on centralized bus control, assumes that data can also be transmitted within closed control loops. To achieve the required efficiency, protocols are implemented in specific ASICs differing in functionality. The FULLFIP ASICs include the standardized functions of layer 7, layer 2, and (in part) layer 1. This approach supports the connection of simple and inexpensive field devices (simple sensors) and minimizes the energy requirements of the interfaces. The decision to use special ASICs means, however, that they must be continuously modified to keep up with changing technology and standards. Given that international standardization of field buses has not yet stabilized, this point may be a problem.

The Route to Open Communication at the Field Level. Open communication at the field level means a consistent, internationally standardized protocol environment allowing field devices and plant computers made by a wide range of manufacturers to be linked to one another. This is particularly important at the field level, because a division of labor between manufacturers is natural and unavoidable in the area of field devices. Open communication has not yet penetrated into the production control and process control levels, but this fact cannot conceal the fundamentally different situation at the field level. Accordingly, manufacturers of field devices have not failed to come up with suggestions to remedy the lack of unity in the world of field bus definitions.

For example, the EUREKA field bus project has the goal of evaluating present field bus concepts and thus promoting the standardization of device interfaces to field buses. Another approach is embodied in the ISP project (Interoperable Systems Project), an international initiative by leading manufacturers of instrumentation and automation hardware wishing to create and standardize a field bus definition optimized for industrial applications on the basis of experience with existing field bus definitions.

The international standardization of field bus systems is proceeding in IEC TC65/SC65C, which is collaborating with the American standards body ISA. The ISA SP50 working group is creating a field bus specification for use in

international standardization. The H1 and H2 performance classes defined by ISA SP50 have already been mentioned. In 1989, ISA SP50 attempted to harmonize the discrepancies between the access control methods (layer 2, MAC) in various field bus definitions. No final result has been achieved, but there is a trend toward "distributed" access control as set forth in IEEE 802.4 or ISO IS 88 024 and used in PROFIBUS. The actual linking functions on layer 2 (LLC) have also been specified; the objective is to unify the most important mediation functions in all field bus proposals while simplifying these functions and thus improving their efficiency. On the whole, there is a trend toward the harmonization of field bus proposals, although the effect of existing national standards and international industrial cooperation on the likelihood of an international standard being accepted must not be underestimated.

The European Commission supported (under ESPRIT) the FICIM project (Fieldbus Integration into CIM) in order to promote the harmonization efforts discussed. From November 1990 to November 1992, the properties and interoperability of the two European field bus specifications (PROFIBUS and FIP) were tested in a pilot installation. The project had the participation of industrial companies as well as NAMUR, the Standards Working Group for Measurement and Control Engineering in the German Chemical Industry. The application functions and application standards were to support and insure the integration of information from these two field bus systems into a CIM system, independently of the lower field bus layers. The pilot phase of this project showed that such an integration goal is indeed achievable. The pilot facility is therefore being used for further studies of the interoperability of field bus systems.

The certification of field bus implementations for conformance to the standardized protocols is regarded as important in all field bus projects. Specifications and implementations of conformance test systems for all layers now exist for the FIP bus and the PROFIBUS. The Upper Tester, that is, the part of the test system above the protocol layer being tested, presents a special difficulty here. Because it is expected that field bus protocol implementations will be optimized for medium-sized and small intelligent field systems, the formerly usual (in MAP) configuration of the Upper Tester on the field bus device under test is no longer possible. The standardized conformance test for such devices thus includes an "Upper Tester Agent" (UTA) on the field bus device; through the field bus, this communicates with the actual Upper Tester on the separate test system.

The wide range of efforts to unify standardization work now in progress, and also to insure conformance of field bus components to the standards, suggests that open communication at the field level can be realized despite the variety of approaches now used. Manufacturers and users in the field of industrial technology should provide intensive support to this development work, since it is an important prerequisite for managing the complexity of future industrial control systems.

Again, a meaningful solution will be obtained only when the information model providing a semantic description of field-level problems has been adopted (see Chap. 2 and Section 5.1).

8.7. Quality Assurance: Conformance and Interoperability Tests

When computer communications equipment made by different manufacturers is used, the user must be able to rely on correct implementation of the protocols. The current state of the art does not allow a formal specification and thus an automatic verification of complex protocols, and so protocol products have to be tested with a standardized set of test cases. These "scenarios" define status data, parameters, and function calls, with whose aid all relevant protocol functions and protocol states can be tested as completely as possible or necessary. A protocol product that passes these tests is said to "conform" to the protocol specifications. If these specifications are taken to be complete and correct, a conformant protocol product will be able to communicate with any other corresponding protocol product.

In a full MAP/TOP or field bus protocol implementation, all protocols at the various levels must be tested. Figure 301 shows the general procedure for conformance tests [612]. The protocol being tested ("implementation under test") is enclosed by a test frame consisting of an upper tester (UT) and a lower tester (LT). While the LT responds to the test protocol in a well-

defined way and detects the reactions of the protocol, the UT interacts with the protocol as if it were a protocol product on the next higher level. The UT is assumed to function without errors; this supposition is justifiable only because the UT merely provides certain interface conditions (ASP = Abstract Service Primitive) and need not exhibit the full functionality of a protocol.

Figure 301. Principle of conformance testing [612]
ASP = Abstract Service Primitive

A test coordinator makes certain that the test scenarios set forth in the conformity test are run, causes the responses of the specimen to be stored, and interprets the test results. Interpretation consists of comparing the reactions of the specimen with a predefined set of expected reactions. The conformance of the protocol product or the presence of implementation errors can be deduced from this comparison.

The fact that protocol products have passed the conformance test does not necessarily guarantee their interoperability. Like any other test, the conformance test is incomplete; what is more, it cannot be more complete and correct than a possibly incomplete and inconsistent protocol specification. This uncertainty can be reduced only by additional interoperability tests.

An interoperability test studies the actual interoperability of protocol products, that is, their real ability to interact in open networks. Interoperability depends on conformance to protocols but also on the matching of parameters that can be adjusted when the protocols are run. In this context, the term profile means an application-specific selection of parameters and functions of a protocol in accordance with a standard. Depending on the ranges of variation of such parameters, different profiles may conform to the standard but not be interoperable. The problems associated with the range of options in profile definition are not discussed further here.

A final key aspect of the serviceability of protocol products is efficiency and performance. Even given correct and conformant protocol implementation, interoperability can be significantly impaired by, for example, wide differences in timing between protocol products. In future, accordingly, standardized interoperability and performance tests will be defined.

An interoperability test system must establish a connection between the protocol components being tested and monitor the resulting flow of data and information. The use of expanded lower testers (cooperating with a communications observer) is conceivable. The interoperability tester compiles the results from the lower tester and the communications observer.

While conformance tests are done against a (possibly partly formal) protocol specification, the interoperability test deals with communications aspects that cannot be so well specified. It is thus much harder to standardize this kind of test. The user of communications protocols, however, sees interoperability as the proper acceptance criterion for protocol products; this is why work is under way to standardize these tests.

8.8. Methods and Tools for Protocol Specification

The preceding sections have made it clear how crucial the degree of formalization of protocol specifications is for the correct implementation of protocol standards. This section describes some procedures and aids now being used in the specification and implementation of protocols and in test systems. The protocols in question are those in the context of the ISO – OSI reference model [598].

These protocols [598] define services that can be described by the functions invoked and the data exchanged. Services are composed of service elements such as establishing and dropping connections, transferring data, and exchanging acknowledgements. Such service elements are deemed indivisible sequences of events and must

Figure 302. Representation context [616]

be implemented in a proper way with regard to fault tolerance and consistency requirements. They are neutral with respect to the data or function calls mediated by them.

Service elements are based on "service primitives," that is, functions such as "request," "response," "indicate," or "confirm." In presentday protocol specifications, these service primitives and thus the service elements built up from them are commonly described in natural language. In this way, a formal specification of the functional (procedural) part of protocols is not usually stated, notwithstanding the fact that these functional (procedural) parts of protocols represent finite automata. The form of description as a finite automaton is, however, used only in exceptional cases and for subfunctions. One important reason for this situation is the complexity of the automata, whose many and varied options make them hard and inconvenient to describe in the form of states and changes of state. Protocol Data Units (PDUs) exchanged with the aid of the service primitives, on the other hand, are now specified formally. A "language" of abstract syntactical notation is available for this purpose; ISO has standardized it under IS 8824, and it has become known under the name "ASN.1" (Abstract Syntax Notation One) [613]. Advantage has also been taken of experience gained in the informatics field with various higher-level programming aids and their data structure description methods.

At present, ASN.1 is used chiefly to define PDUs in protocols at the applications level of the ISO model [614]. As Figure 302 shows, applications programs or applications entities exchange information by means of PDUs. The ASN.1 language makes it possible to formulate these PDUs in the abstract manner standardized by IS 8824. It should be ensured that the meaning (semantics) of the PDUs in a given local applications syntax and in the abstract ASN.1 syntax remains unchanged. Thus, semantics-preserving transformations between the syntax of any local language and the abstract ASN.1 syntax must be defined.

The transmission of these PDUs via a communications system requires a concrete syntax, called the transfer syntax, that is understood by both communications partners. The transfer syntax must be defined at level 6 of the ISO model. Accordingly, ISO has standardized a "concrete transfer syntax" under IS 8825 [613], just as the abstract syntax is standardized under IS 8824. Thus, for PDUs actually to be transferrable between two applications entities, the abstract PDU definitions notated in ASN.1 must be translated from the real local syntax of each applications program into the IS 8825 transfer syntax. This assignment of a transfer syntax to an abstract syntax is called "representation context."

It is significant that the representation context standardized by ISO for ASN.1 is not a unique standard valid for all time. Other representation contexts especially suitable for certain applications areas can be defined later on; this is particularly important in connection with the companion standards discussed in Section 8.4. Thus, in order that one applications-specific representation context can be replaced by another for communications between applications program, every communications process begins with the

Figure 303. Implemented architecture of conformance testing

negotiation of the proper representation context. One example might be an exchange of communications of applications program systems between partners in the realm of process control engineering and partners in the realm of office communications. The difference in encoding conventions (e.g., measured data or CAD data) means that the representation context must be adapted.

There is already an alternative to the representation context ASN.1/Basic Encoding Rules, in the form of the "default context," which is used whenever no special representation context has been negotiated. This is the case in particular when a connection is being established. The default context, however, contains neither an abstract syntax notation nor a concrete transfer syntax. The unstructured bit stream between the two applications programs must be directly interpreted by the programs.

Because the PDUs of important MAP applications protocols, especially the MMS (Manufacturing Message Specification) services, have been specified in ASN.1, it is an obvious step to employ the same representation context for specifying the conformance tests for MMS. As Figure 303 shows, the conformance tests for the protocols MMS, Network Management (NM), and Directory Service (DS) are based on a set of ASN.1 tools with whose aid the test parameters and dynamic test cases for these three protocol groups have been formulated and processed. The

system of tools for conformity tests, as shown in Figure 303, were devised by the Institute for Information and Data Processing of the Fraunhofer Society. Though not completed at the time, they were used successfully in the conformity test at IENE '88 (International Enterprise Networking Event) in Baltimore, June 1988. It is expected that the representation context based on ASN.1 is sufficiently powerful to cover other Companion Standards as well. The standardization of PDUs, at least for the protocols named, is thus formalized to the extent that conformance tests can be derived from the actual protocol definitions in a direct manner, without substantial recourse to natural-language definitions.

8.9. Steps toward Computer-Integrated Production

Consistent information integration in production companies is the objective of the computer communication utilities derived and discussed in this chapter in the context of information logistics. While very important, they are by no means the only tools available for reaching this objective. Computer-Integrated Production (CIP) can be achieved only through collaboration between disciplines: production engineering (manufacturing engineering, control engineering, logistics, production planning, etc.), communications engineering (digital data transmission), and informatics (systems engineering, hardware and software technology). This integration of methods, in which information logistics is merely one part of the needed methodological edifice, is only just starting to gain support from products on the market and certainly cannot be achieved through standardized communications protocols alone. The custom CIP solution for a given plant often constitutes an analysis and modification of internal structures and modes of working.

The translation of such an internal reorientation to the use of computer communications techniques must take place in a continuously changing environment. Thus, MAP Versions 2.1 and 3.0 are not compatible; an early involvement in this protocol world gives rise to valuable experience, but also to a continuing need for new investment in more-advanced protocol products. Even within General Motors, initial experience with MAP was problematical. But it would be wrong to think that these unavoidable startup difficulties in a very complex field represent a failure of information integration. Outcomes of this experience have included more protocols on the applications level (or on all protocol levels at once), such as Network Management or Directory Service. In this way, gaps in the MAP/TOP definition are closed and the use of computer communications is facilitated.

The same applies to the present status of field bus standardization. Again, international differences in the view of applications requirements and product line definition must be ironed out in such a way that a single set of international standards can be devised in a usable form. The reaction of industrial firms to the very protracted standardization process shows once more that industrial users and manufacturer of communications systems are interested in open systems of information logistics.

All this development of tools will, however, be fruitless if users of CIP do not acquire the knowledge and training they will need to understand the total system. Along with education within the corporation, occupational training has a role to play. At the same time, there is a need for competent, neutral sources of advice. It is precisely small and medium-sized companies that lack the personnel resources to keep up with the rapid development of information integration and turn it to their own use, even though this assimilation is urgently needed to insure the future of the company's production and products. Regional sources of advice (chambers of commerce and industry) as well as research institutions cooperating with industry are increasingly available.

The path to computer-integrated production can be discerned today. It will lead, with much difficulty and many setbacks, to an improvement in the competitiveness and market position of those companies that have the commitment, creativitiy, and perseverance to follow this path.

9. Computer-Aided Methods

9.1. Principles

Coming years will see greater and greater importance attached to the use of computer-aided

methods and computerized tools for the design, erection, operation, and maintenance of processing facilities. The steadily increasing number and complexity of industrial plants and the requirement for complete, current documentation will generate a volume of work that could scarcely be handled without computer support. At present, however, the ratio of computer-aided tools to demand is still fairly small.

As the needed computer-aided engineering (CAE) systems are developed and selected, it is crucial that the engineering disciplines involved must be treated not as individual, independent working groups but as the intermeshed system they really make up, in which the results achieved in one discipline influence the work of the others. This does not mean that one "universal" tool has to be devised for all engineers. The model of a well-filled and organized "toolbox" appears to promise better success. Such a box contains a special tool for every job. The tools, however, are designed so that they all share consistent interfaces and thus can be combined with one another at will. Any problem that arises can thus be solved in optimal fashion; if the objective is changed, the "toolbox" can be adapted to the new situation through the modification of an existing tool or the addition of a new one.

This book does not deal with computeraided design tools for plant engineering (e.g., INTERGRAPH).

9.2. System Analysis

The background for system selection must include the formulation of overall objectives and possible interfaces.

The overall objective is broken down into partial objectives, which in turn are refined further into tasks. This procedure is continued until the individual tasks are manageable in their complexity and the functions needed for accomplishing them can be described along with the resulting data flow patterns.

To make this task analysis easier for the user and permit an unambiguous interpretation of the results, a variety of methods have been devised for displaying the process in graphical form with defined symbols. The best-known methods are structured analysis and design technique (SADT) [617] and structured analysis (SA) [618]. Either method can be carried out manually with pencil and paper, but increasingly they are embodied in software packages that make it possible to run these analytical tools on PCs and graphics workstations.

In what follows, the SADT method is briefly illustrated in a simplified example.

The essential elements of the SADT diagram are labeled boxes and arrows. Boxes symbolize activities (functions), while arrows stand for data and information and thus characterize the interfaces between boxes.

The following rules also apply:

- Input information always enters a box from the left, is transformed into output information in the box, and leaves the box on the right.
- Controlling information influences this transformation and may also be used per se in producing the output. Such information always approaches a box from above.
- The function of a box may be supported by mechanisms, which are optionally represented as arrows entering from below.

A model generated by SADT is a structured breakdown of a problem, represented as a hierarchically ordered sequence of diagrams. The topmost level of the hierarchy is a diagram with a single "black box" representing the total system, showing its connections to the outside. On the next level, this black box is broken down into a number of boxes; the same procedure is continued down the levels.

Figure 304 shows, in simplified form, the top two levels of an SADT model representing the engineering functions involved in the design, erection, and operation of a process plant.

The upper part of the figure shows the black box representing the overall system, with interfaces to the outside world. In the bottom part, the overall problem is broken down into the following subproblems:

- Design the process
- Design the plant
- Erect the plant
- Operate the plant

In the graphical presentation, the functions (boxes) are normally arranged on the diagonal from top left to bottom right. The order of functions is governed by the required flow of information and data, shown as arrows between the

Figure 304. A SADT diagram (top two levels)

boxes. Feedback of information may also occur, in which case the procedure becomes interative. Interfaces to the outside world are also shown in greater detail.

Now each of the functions is further broken down in diagrams and documented. Obviously, complex problems yield many diagrams, all partially interdependent. Hence, if changes are made, these relationships must be taken into account and the appropriate corrections performed. The use of such a method thus calls for a considerable amount of administrative effort; on large projects, this is difficult to accomplish without suitable computer support. However, the implementation of a software project is virtually impossible without a prior system analysis.

In parallel to the design of the function model just described, it is necessary to define the overall system data model that applies to all functions. Only in this way can proper sharing of information among functions and consistent data management be insured. As a rule, the data model is set up as an entity-relationship diagram with data dictionary. Programs for this design task are also on the market; in many cases they are already combined with SA or SADT tools to make up software development systems (see also Chap. 2).

9.3. CAE System for Process Control Engineering

Within the overall system, the individual CAE tools used in the several engineering disciplines must have compatible interfaces. In addition each tool should have the optimal functional scope for the objectives of the field in which it is used. The special requirements on such a CAE system for use in process control engineering are therefore discussed in what follows.

A CAE system for process control engineering must support both the design and the later operation of the process measurement and control system, including maintenance (Section 11.4).

This latter aspect is particularly important here. Over a span of years, the design changes in an onstream plant due to detail improvements or process changes can easily loom as large as the original design. At the same time, the documentation must meet stringent standards of currency and consistency, since these changes generally must be performed while the plant is on stream or during brief shutdowns (see Section 3.5).

The CAE system must therefore be able to handle data having a variable and complex structure and to afford assistance in the processing of such data.

Process measurement and control functions are implemented in hardware and software. In practice, it has been found that a subdivision of the task into hardware design and software design is useful, and in fact these sub-tasks can even be carried out by different persons in the case of large projects. Both areas, of course, have access to a jointly defined interface, but are otherwise not temporally linked and can therefore work independently of one other.

The hardware data to be managed in the CAE system can be broken down into three classes:

- Station data: all information describing the task and the functional design of a process control station. As a rule, these are documented in station data sheets and station diagrams (see Figs. 339, 340, 341, 342).
- Device data contain the exact technical specifications of the devices employed. These serve as the basis for later procurement.
- Position data describe the configuration of the devices in the facility and contain the infrastructure created by the master cable. Typical forms of documentation are setup plans, terminal allocations, and cable plans.

The data describing the software have a different structure. Generally, modern process control systems have modular software. The modules are linked to one another and arranged into various levels of a hierarchy, depending on the task. The lowermost level is made up of modules that implement the functional design of a single process control station (Section 4.4). Higher-level modules coordinate the work of lower-level ones. Each module is composed of functional building blocks, which are the smallest software elements of a process control system. The most important documentation forms for software are function charts, logic diagrams, and element structural plans.

All these data groups are closely linked; together, they represent all the information about the process control equipment. In what follows, they are treated together under the term "project data." As a rule, these project data are managed by a database system (Chap. 10).

9.4. Structure of a CAE System

The ideal structure of a CAE system as shown in Figure 305 reflects the constraints discussed above.

Figure 305. Structure of a CAE system for process control engineering

The heart of the system is a relational database, which contains the computer model of the planned equipment. All manipulations of the database take place interactively; depending on the task, graphical interfaces may be used.

At the start of the design work, basic information for the project is acquired from the other departments involved. The most important source is the process control tender specifications, which set forth requirements on the pro-

cess control devices to be implemented as well as their interconnections. Information is also required from the plant database, which supplies technical data on the plant sections affected as well as ambient conditions where the process control device is to be installed.

On this basis, the designer begins with the detail design of process control devices. This procedure is interactive and employs a graphical user interface. The system offers a number of tools that can, for example, prepare plans, enter specification data, define cables, or copy entire plans or cabinet terminal allocations. These manipulations gradually build up an internal model of the process control equipment in the database. Every interaction on the screen brings about a corresponding modification in the database.

This internal (computer) model also serves as the basis for all documentation. The various documents are merely the results of various inquiries formulated to the same database under various criteria. In this way it is insured that any subsequent changes will automatically be incorporated into the next round of documentation.

A CAE system with this level of complexity may consist of a number of largely independent modules, all of which communicate with one another through the common database. One possible subdivision into task areas is as follows:

- Hardware design
- Software design
- Procurement
- Installation

These are largely independent as far as processing is concerned and have access to one another only through a few well-defined interfaces. Accordingly, independent solutions are now on the market for certain of these task areas. When such products are employed, however, special attention should be focused on the possibility of later integration into an overall system.

Because process control devices cannot be designed and operated in isolation from the plant as a whole, smooth communication should be insured between this process and other departments, such as plant design, process engineering, purchasing, and maintenance [619]. The only way to be certain of this is to define a common data structure within the company: the company data model. Without such a data model, the danger exists that terms and information might be differently interpreted in the several systems, so that consistent data management would be impossible.

A crucial problem for the acceptance and efficiency of a CAE system is whether and to what extent the system user interface is adapted to the user's methods. Typical users impose varying, and in part inconsistent, requirements.

One user is the design engineer, who quickly becomes an "expert" through daily work with the system in a variety of modes, can operate it "in his sleep," and therefore wishes to get results quickly, with the fewest possible manipulations, and without having to read help messages.

In contrast, there is the operating engineer, who is confronted with the system only occasionally and briefly, for example during process upsets and when design changes are being worked out. The system should prompt this user in an intuitive way, with extra help functions, to avoid a prolonged learning process and the study of manuals. Because the drawing is the most comprehensible "language" in conventional design work too, it is an obvious step to design the entire user interface and system tools for largely graphical operation. In this way, the user's previous working methods are largely preserved, so that learning the system can be accelerated.

The use of hierarchically structured menu trees can drastically simplify the operation of choosing from a large number of devices or symbols. If the menus and the underlying database are cleverly designed, progressive narrowing of the field quickly leads to certain individuals without the use of lengthy catalogs and lists. This technique is widely used in modern systems [620].

9.5. Aids for Hardware Design

A number of CAE systems for process control hardware design have appeared on the market. They take two distinct approaches to implementing the task. One is to combine independent standard programs for database applications and 2-D graphics, using suitable auxiliary programs to link and supplement the commercial software. The other approach leads to an integrated system, in which the graphical tool is directly linked to the database and each is independent of the other. Both solution approaches will be

Figure 306. Structure of a combined CAE system

described in what follows, and their advantages and disadvantages will be discussed.

Combined CAE System. A combined system includes a free-standing, independent software package for alphanumeric tasks and one for graphical tasks, each package having its own data management features (Fig. 306).

Basic information contained in the alphanumeric package includes specifications on standard devices (process control equipment data; Figs. 10 and 339). Typical configurations, with information on combinations of devices for stated purposes, are also included as standards. In parallel, the graphical program package must have the respective symbols for the individual devices as well as typical plans for device combinations. It has to be explicitly verified that the typical configuration and the typical plan are logically consistent, since this forms the basis for subsequent automated processing (see also Figs. 340, 341, 342 and 61).

The first step in design is to input the process control stations, in the form of a station list, into the alphanumeric software and assign a typical configuration to each station on the basis of the task statement. These data are supplemented by structural information, such as the terminal allocations of cabinets and racks and the master cable connections. The devices used may also be specified more closely. Once the station and configuration data have been prepared, they can be exported to the graphical side with the aid on an auxiliary program. The respective plans are now prepared. Infrastructure information, such as terminal codes and the like, is entered into prepared text placeholders. The information managed in the alphanumeric module can thus be output as documentation along with the graphics.

There are a number of advantages to this approach. The use of common standard programs makes it possible to assemble such a system at relatively low cost. Because the programs do not have to run in parallel, the system can be and usually is executed on a PC with the MS-DOS operating system. The system as a whole is highly modular in structure, and the user can generally expand it with additional functions.

These advantages are partially offset by several drawbacks. The use of several software packages from different publishers means that the user must be familiar with the diverse operating concepts of the programs. Because configurations and plans are generated in different programs, there is a danger of input errors, which can lead to inconsistencies.

A combined CAE system thus has its strengths in the design areas, where a high degree of standardization is possible. If subse-

quent changes not complying with the standard are made, however, corrections must be made in both the alphanumeric and graphical components of the documentation.

Integrated CAE System. The integrated solution features a direct link between the graphics package and the database. Graphical manipulations thus influence the database contents immediately, while alphanumeric inputs influence the graphical representation on the basis of certain rules. This close connectedness both insures the consistency of the data and makes it possible to carry out plausibility checks. Interactive operation builds up an internal model of the process control equipment, which serves as the basis for all interpretations. All documentation, whether in graphical or alphanumeric form, is derived from this model (Fig. 307).

Figure 307. Structure of an integrated CAE system

The close coupling of graphics and database system usually requires the use of a multitasking operating system. The graphics packages employed are specially developed software with special provision for interaction with the database. UNIX graphics workstations serve as the hardware component.

The advantages of the integrated approach lie in the consistency of the data. In case of subsequent changes, corrections are essentially needed at just one place.

Because of their more complex structure, integrated systems are necessarily more expensive than combined ones. What is more, high-performance hardware is required if an acceptable response time is to be achieved [620–623].

Over the long term, the integrated CAE system is the better solution. Its present cost disadvantages are being offset by technical developments in the workstation market.

9.6. Aids for Software Design

Hierarchical Organization of Software. The principles of functional organization and progressive refinement have been tested in practice for the description of complex relationships (see Chap. 2). A good example of such a procedure are the design steps involved in the development of a complex integrated circuit such as a CPU. First, the required functions are represented in the form of modules at a fairly abstract level, and the requisite interactions between these modules are described. Next, the internal structures of the individual modules are established; the same principle is applied recursively in this step. The objective is thus narrowed down to the level of single transistor functions. In the subsequent fabrication operations, the complex functioning of the circuit is achieved through the combination and interconnection of many very simple subfunctions.

A similar procedure can be applied to the preparation of software for process control systems. The overall task is broken down into sub-tasks with well-defined interfaces (see Section 5.2). By narrowing down the description, one ultimately reaches the lowermost level of abstraction, which in the case of process control systems is formed by the components and logic functions available. The software for a system is finally written by appropriately combining these basic elements (Fig. 308).

If there is so much similarity in the procedures, the question arises whether parts of the highly advanced commercial CAE tools for circuit design might not be usable in modified form for process control system software development. In what follows, the minimum requirements on such a tool are stated briefly.

Figure 308. Progressive refinement of a software structure

Graphical Generation of Function Charts and Structural Diagrams. The building blocks or logic functions of the process control system, as furnished by the publishers, form the basis of the applications software. The stated task is accomplished by combining these, in suitable form, to make structures. The most important aid in design and subsequent maintenance is the function chart or structural diagram (Figs. 59 and 343). It shows graphically all the components used, with their interconnections and parameters. The creation of a graphical tool for generating these diagrams is crucial. The element symbols are selected from a library and placed on the screen interactively. The connections between elements are generated by constructing lines between the element terminals. Parameter values can also be interactively assigned to specific element terminals. The logical content of these diagrams must be determined by the system and automatically translated into a sequence of programming instructions for the process control system. Plausibility checks can be performed to eliminate programming errors

directly at the source. This procedure simultaneously insures consistency between the program and the documentation (see Section 10.6).

The CAE tool must support the method of successive refinement described above. The user must be able to generate abstract modules and their connections in a plan without needing to know their internal structures. Internal structure can be represented in a later diagram; the system automatically takes care of cross-referencing. In this way, complex structures can be detailed step by step, down to the component level. During code generation, the system must recognize and take into account information about the entire hierarchy of diagrams.

Another important point is the use of "typicals." These are multicomponent structures that can be used without alteration in many diagrams. Constructing a good library of typicals can drastically reduce the required design effort. At the same time, it leads to standardized software, since a fixed combination of elements can always be used for like functions. Such a capability must therefore be implemented in a CAE tool (see also Section 4.4).

Apart from building blocks defined specifically for each process control system, there are system-neutral descriptive forms for logic and sequential control systems. The appearance and interpretation of these are specified in ISO and DIN standards. It should therefore be possible to program controls with the aids described above, using the standard symbols. The translation to the language of a particular process control system is another function of the CAE tool.

Construction of Screen Diagrams. Like the preparation of component-oriented software, the programming of the user interface for a process control system is a particularly critical point (see Section 11.2). At present, this represents a major design effort, requiring support by CAE tools. Graphical plant diagrams used in interactive mode have come into widespread use in the user interfaces of process control systems. The graphical design of such images should be performed with tools whose quality and ease of use are consistent with those of commercial CAD systems. The definition of dynamic displays or controls might be done by marking the position and assigning the variable name. Diagrams constructed in this way should be usable for all components of the process control system without case-to-case modifications.

Documentation of Existing Facilities. A special problem arises when existing plants must subsequently be documented (see Section 3.5 and Chap. 10). Often, the current program no longer corresponds with the original documentation because changes have been carried out commissioning or maintenance. All process measurement and control systems can document the current program structure in the form of component and configuration lists. This form of documentation is, however, difficult to understand, and in practice it cannot be employed for troubleshooting. As a rule, therefore, there is no alternative to changing or regenerating function charts and structural diagrams on the basis of the current lists, but this procedure is time-consuming and expensive. Users are therefore demanding automatic graphical documentation of the current state of a process control system.

Synthetic diagram generation on the basis of information present in the control system constitutes a basic problem. Because the system contains no information about the original form of the diagram, the component and terminal positions needed for the representation must be determined by using algorithms such as "information flow top to bottom" and "minimize feedback paths." The consequence is that a synthetic diagram with given content may have a different graphical organization from a hand-drawn diagram. Furthermore, even small changes may alter the positions of some components relative to the old version because of differences in evaluation in the placement operation. This property may interfere with the immediate re-identification of a circuit. Nevertheless, retrospective graphical documentation can insure complete consistency between the documentation and the current program. For this reason, users are willing to tolerate the disadvantages of retrospective documentation until a better alternative becomes available.

System-Neutral Programming. Various manufacturers of process control systems have developed CAE tools, each tailored to a particular system. Although such a package provides effective support to the user, it also poses a new problem. Large firms and large engineering

offices, which usually prepare designs for a variety of control systems, would have to employ a large number of diverse, system-specific CAE systems in order to simplify software writing. Because these systems are mutually incompatible, porting existing application software to a new system ultimately means doing a complete redesign. Users have therefore welcomed the efforts of the IEC to devise a neutral, standardized programming language for process control systems. With such a language, system-independent and thus portable technology applications could be developed. Using such packages, the user could eventually perform tasks in a problem-oriented way regardless of which CAE system was in use.

9.7. Outlook

The development of CAE systems has been strongly influenced by rapid advances in computing hardware and software. If users are not to find themselves isolated in a few years and restricted to possibly obsolete computer systems, modern CAE systems must be made independent of both hardware and software. This objective can be achieved only by means of international standards.

In the operating systems area, UNIX Sys. V or OSF can serve as a standard. Most publishers have now adopted the MIT X-Windows System as the basis for the graphical user interface. A number of competing tools are available for the actual design of the user interface, but OSF MOTIF is emerging as the favorite. A CAE system developed with these tools can thus be regarded as having a good future.

One particularly critical point is the data management problem. Because plant design data generally must be kept for 20 to 30 years, stringent requirements apply to the dependability and development potential of the database program publisher. At the same time, exotic data structures should be avoided so that data can, at least in principle, be imported into a different database system. In the context of workstation networking, the potential of decentralized data storage should be investigated.

Graphical workstations, connected to one another and to service computers by local networks, will become the standard hardware. The simultaneous rapid rise of computer performance and decreasing hardware costs will allow use of high-performance solutions. The high requirement for storage space will be partly answered by advances in rewritable optomagnetic discs, which offer high data security and long-term stability.

10. Design and Construction of Process Control Systems

10.1. Principles

The previous chapters have described the functional and hardware elements of process control engineering. This chapter deals with the design and construction of process control facilities.

It is seldom that process control problems arise in isolation. As a rule, they are embedded in an overall problem. This may concern an investment project in the field of chemical plant construction; process control engineering then represents one component of the problem, while other disciplines such as machinery and apparatus, building construction, and piping are also involved.

In the design and construction of plants, a distinction is made between new construction and extension or reconstruction.

Extension and reconstruction activities are generally more difficult to plan than new construction projects, since interfaces to existing plants have to be taken into account and the existing infrastructure and engineering must be modified. The overall extent of the work usually only becomes apparent when planning is already under way. A complicating factor is that economics often dictates the incorporation of changes while the plant is on stream or during shutdowns. Because the scheduling and duration of shutdowns is governed chiefly by operational constraints, however, planning of schedules and resource utilization must be done with special care (Section 10.2).

New construction projects based on processes already in use within the company are generally simpler.

The handling of processes new to the company (i.e., created in process development or purchased from a licensor) is more difficult. Scaleup problems can involve substantial risks.

Figure 309. Phase model for chemical plant construction projects

Figure 309 gives a model for the implementation of chemical plant construction projects. The main blocks represent

- Project management
- Project planning and execution
- Quality assurance

The design and construction of plants is carried out in the framework of projects. Project management (Section 10.2) accompanies project activities, coordinates the work, and monitors compliance with directives.

In Germany, the usual approach project planning and execution is based on the regulation governing architects' and engineers' fees [624]. It is useful to illustrate the procedure in the form of a phase model, which breaks tasks or functions down into phases and steps and shows their outcomes (Fig. 309).

Note that the phase model represents an ideal. In actuality, the several phases merge continuously and may even overlap. Feedback and iteration between phases are also common. Inter-

faces between disciplines further complicate the process.

The phases can be grouped into two large phases on the basis of the problems to be solved; these are called the decision phase and the execution phase [625].

The decision phase (Section 10.3) involves the conceptual work. The task is formulated here; it can be thought of as the mission to be performed in the course of the project. The written description of the problem is called the performance specifications (Section 10.4); it forms an essential component of the decision phase.

The performance specifications give rise to the "binding concept," embodied in the specifications, which describes how and with what resources the stated task is to be performed (Section 10.4).

The concept has long-term consequences, since it influences the economics of the plant throughout its service life. Identifying the concept is therefore accorded special importance. This step requires great care and is supported by analyses of alternative solutions as well as an examination of the overall project.

One task may admit of several solutions, among which the optimal one for the company (from both economic and technical standpoints) is to be selected. The selection criteria may include

- Attainment of targets
- Fulfillment of economic criteria (Section 10.4)
- Compliance with regulations (Section 10.6)
- Availability of plant
- User-friendliness
- Use of proven techniques

The total analysis of all disciplines involved in an investment helps to prevent the overall project being harmed by suboptimization of individual disciplines.

The binding concept is the basis for corporate management's decision to proceed further.

The execution phase (Section 10.5) is oriented toward workmanship. Using results derived in the decision phase, it creates a functional plant.

When the chemical plant design and construction process is divided into decision and execution phases, with the stress on holistic analysis and conceptualization, the result is that the problem is handled in a fundamentally different way from what used to be common (see also Chaps. 2 and 8).

In the past, planning for certain functional specialties, including process control engineering, often caused delays in other parts of the process, such as plant design. The tasks of the "trailing" discipline were sometimes formulated from the standpoint of the "leading" one.

A holistic view of the task could scarcely come about in this way. If such a view was formed in the course of the project, any corrections arrived at through such an analysis, no matter how logical and necessary, were not carried out, simply because the planning processes in the several disciplines had reached such very discrepant stages by that time that revision of existing plans by the methods then in use could not be justified in terms of cost and lost time. The systematic use of data-model-oriented planning in plant construction, such as the Intergraph plant design system, makes it possible to implement changes such as those described in Chapter 9.

In the past, compromise solutions replaced logical, holistic solutions; suboptimization of individual disciplines was the rule.

The complexity and diversity of techniques now in use, together with the resulting interdependence, have led to continuous interaction between disciplines, virtually barring such an approach.

Only the analysis of the project in its totality, coupled with the conceptualizing approach and an intensive quality-assurance effort (Section 10.6) going along with the execution of the task, can satisfy the requirements imposed on the economics, safety, and environmental compatibility of engineering solutions today.

10.2. Organizational Requirements

The organizational concept in the execution of projects is called project management.

The term "project" refers to the performance of individual tasks bounded in time and having clear objectives; these tasks may further be characterized by features such as interorganizational components, many involved divisions, high level of complexity, and possibly heightened risk [626].

Various types of project exist, including

- Construction projects
- Plant projects
- Organizational (management) projects
- Research and development (R & D) projects
- Software projects

In general a project is the complete temporal framework of conditions of all substances for the realization of tasks represented by functions [627]. "Substances" are suitable procedures, systems, and elements (Figs. 10 and 65) and are also called "resources"; Figure 310 illustrates this relationship.

Figure 310. From problem to plant

In order to achieve the project objective, these resources must be procured, combined, coordinated, and utilized. Project management is responsible for these functions.

Organization. The organizational setup of project management differs from the "line" organization generally found in companies.

Organizational Forms. A variety of organizational forms are seen in project management. The three most important are briefly described below [628].

An across-lines form, also called "matrix" project organization, has proved especially successful (Fig. 311). The customary line organization is retained but is enlarged by a further dimension – project management. Certain aspects of the project, such as technical responsibility, remain under line jurisdiction; others, such as project responsibility, are transferred to project management.

This form of organization offers the advantage that personnel resources are optimally utilized, since employees remain in the project only as long as they are needed. As a result, specialist knowledge and special experience can be more easily brought in as well as transferred to subsequent projects. These advantages are partly offset by some drawbacks, in particular jurisdictional conflicts between line and project management and the relatively great effort required to demarcate responsibility.

Figure 311. "Matrix" project organization [628]

Figure 312. "Straight" project organization [628]

The advantages, however, outweigh the disadvantages. The matrix form of project organization has therefore found a wide variety of applications. It has been broadly accepted, in particular, by the chemical industry.

In "straight" project organization (Fig. 312), a separate, independent project line is created in addition to the main lines; project management has its own organization partly similar to those of the main lines. Project responsibility and technical jurisdiction are combined at a single point. Quick reactions are possible when difficulties arise in the planning and execution of the project. Against these advantages stand difficulties in recruiting personnel at the start of the project and in keeping these people occupied after its completion. Straight project organization is mainly used in large, long-term projects.

In "influence" project organization (Fig. 313), project management is simply a coordination instrument, without the authority to issue orders. It tracks progress with respect to schedules and costs and, if necessary, suggests actions to the respective line jurisdictions. Project management has no responsibility for the project; it is responsible only for providing timely information to the line jurisdictions. This arrangement does not favor successful cooperation across lines. When difficulties arise, reactions usually come slowly and delays result.

This form of project organization is usually practiced on smaller projects and projects involving several companies.

Figure 313. "Influence" project organization

Organizational Structure. For project management with matrix organization, especially in the chemical industry, a threefold division of responsibility has proved logical and useful (Fig. 314):

- Project management committee
- Project manager
- Project engineer

The project managment committee is the actual supervisory and decision-making body. It includes the decision makers of the crucial lines involved in the project, i.e., those issuing the order for it and those executing it. The project management committee formulates global mission targets. It monitors the complete and onschedule attainment of these targets, makes the needed decisions when targets come into conflict, and causes these decisions to be implemented in the

Figure 314. Organizational structure of project management

lines. The committee insures the availability of material and personnel resources.

The project manager is responsible for structuring the project. His duties include the definition of sub-tasks in accordance with the project structure. Principal activities are the planning and oversight of schedules, costs, materials and other resources used, and progress. In addition, the project manager sets up and implements the reporting system.

The project engineers support the project manager by providing organizational and technical guidance and oversight to the project teams, which are detailed by the lines to perform subtasks within the project.

The makeup of project management depends on the size and importance of the project (Fig. 315). The "size" of a project can be defined in a variety of ways; for investment projects, the level of investment is the key criterion.

In large projects, the project management committee is made up of delegated decision makers from top management. For small to medium sized projects, on the other hand, decision makers from lower strata of the hierarchy form the committee.

For large projects, a head-office project manager is designated; this person always performs management functions. Smaller projects do not require so much expense for the project management function, and a number of alternatives exist here. One manager can manage several projects at once, or one manager can focus on a single project but add specialist functions to management ones. The manager then becomes a participant in the project. The same holds for the

	Project management committee	Project manager	Project engineer
Key projects, projects of strategic importance	Decisionmakers from top levels in the hierarchy (top management)	o for one project: with pure management function	o for one project: with pure control and monitoring functions
Medium-sized projects	Decisionmakers from middle levels of the hierarchy	o for several projects: with pure management function or o for one project: with management and technical specialist function	o for several projects: with pure control and monitoring functions o for one project: with pure control and monitoring functions
Small projects	Decisionmakers from lower levels of the hierarchy		

Figure 315. Project management organization as a function of project size and importance

Figure 316. Tasks of project management

project engineers: They have 100 % of their time assigned to large projects, a lower percentage for smaller projects.

Tasks. Figure 316 summarizes the functions of the project management committee, project manager, and project engineer.

Major management activities include project structuring as well as cost, schedule, and resource management. Performing these functions requires close cooperation between all the activities involved in executing the project.

Project Structuring (see also Chap. 2 and Sections 3.5 and 4.3). The nature, scope, and complexity of a project dictate the manner and depth of structuring. This activity results in structural charts and can be based on a variety of approaches, with a corresponding variety of structural charts as outcomes [629].

The object-oriented structural chart breaks down the material and immaterial objects to be created by the project into components in hierarchical fashion. Figure 317 shows a portion of such a structural chart for the erection of a chemical plant.

The function-oriented structural chart shows the breakdown of project activities.

The structural chart of technical scope of performance shows what intermediate and final outcomes are to be generated by the project. All documents to be produced, such as reports, plans, drawings, lists, descriptions, certificates, contracts, and so forth are included, regardless of whether they will still be needed after the end of the project.

The last two types of structural chart are seldom made up by themselves; a combined form is usual.

The main goal of project structuring is to determine the total volume of work necessary for the success of the project. In this way, the preconditions for further project planning are fulfilled,

Figure 317. Example of an object-oriented structural chart

Total investment
- Apparatus, machinery
- Buildings
- Piping
- Process measurement and control
- Miscellaneous

Factor $\varphi_1 = f$(structure type, plant type, ...)
Factor $\varphi_2 = f$(complexity, materials of construction, ...)
Factor $\varphi_3 = f$(functional scope, required availability, safety aspects, ...)
Factor $\varphi_4 = f$(...)

$$\text{Total costs} = (1 + \sum_{i=1}^{n} \varphi_i) \cdot S_0$$

S_0 = total machinery and apparatus cost
S_i = total cost of category i
$\varphi_i = S_i / S_0$

Figure 318. Cost estimation by the multiplication factor method

since project structural charts influence, among other activities, the planning of schedules, costs, and resource utilization [629].

The transparency achieved through project structuring makes is possible to identify key tasks. It becomes easier to coordinate project teams and delegate their sub-tasks. Economic, technical, and also organizational risks, such as jurisdictional conflicts between project management and lines, can be delimited. Project structural charts are a prerequisite for effective project monitoring.

Cost management refers to all cost-related activities in the course of a project, such as costing, planning, monitoring, and billing.

Cost management is of central importance for a project. It must cover in detail

- Procurement costs for machinery, apparatus, buildings, process control equipment and systems, infrastructure, and other materials
- Erection and installation costs
- Engineering costs due to planning, design, and administrative activities
- Start-up costs

The specialist literature offers a number of methods for determining procurement costs in chemical plant construction [630]. The accuracy of the results depends on the method used, the depth of knowledge about the project, and other factors.

It is beyond the scope of this chapter to describe all methods in detail. Just two, widely used in plant construction, merit discussion.

The first can be called the "method of multiplication (or ratio) factors." The simplest application of the technique requires a rough, object-oriented breakdown of the overall costs into, say, the categories:

- Machinery and apparatus
- Buildings
- Piping
- Process control equipment and systems
- – Miscellaneous

The machinery and apparatus needed for the realization of a process are the first things to become known during an investment project. They can be calculated from offers or empirical figures and adjusted for inflation and market trends.

The principle of the method is that the costs of all other categories involved in the investment can be determined by using ratio factors based on the costs of apparatus and machinery (Fig. 318).

The person practicing the method needs experience to obtain usable results, since the factors include scope-dependent ranges. For example, office structures must be costed differently from industrial structures, and larger factors should be used for new "green-field" plant investments than for extensions based on existing buildings. The assessment of piping costs depends on, among other things, the complexity of the piping structure and the material of construction. Influences on the ratio factors for process control equipment include functional scope, required availability, and safety aspects.

Experience has shown that the method of ratio factors makes it possible to estimate costs with an accuracy of ca. $\pm 20\,\%$.

The second cost-estimation technique, is "unit-cost estimation." Like the ratio-factor method, it is based on an object structure, but a more detailed one.

The simplest case for cost estimation is the procurement of "substances" (see Fig. 10), provided the quantity structure is known accurately enough (see also Fig. 332).

Figure 319. Example of a cost structure for unit-cost estimation

To every object at a structural level, the technique assigns a price referred to an object-specific unit (per item, unit area, etc.). The total price is obtained by multiplying this unit price by the quantity. For example, a possible cost structure for process measurement and control is shown in Figure 319.

This method is suited both to coarse and fine estimates, since cost estimates can be obtained for virtually any degree of subdivision. The accuracy of estimation increases with the level of detail. At the same time, however, more effort is required because the detailed breakdown calls for thorough knowledge, which can be acquired only gradually and after the project has been started.

The amount of effort can be reduced if the in-depth analysis is restricted to cost-relevant items while only a rough estimate is done for items of less relevance to the cost. This procedure does not result in any marked loss of accuracy. Cost-relevant items are those that make a large contribution to the total cost, for example by virtue of large quantities and/or high unit prices.

Incorrectly determined unit prices have less effect on the estimated cost than does an incorrect quantity structure. Experience indicates that this is where most errors occur.

Multiplication factors and unit prices are obtained by evaluating the invoices for a number of investment projects already carried out, extracting the cost structures, and then taking averages.

Today, installation is rarely carried out by in-house departments, and is mostly performed by contractors.

Installation can be paid for in any of three ways [631]: by expenses, by unit price, or by fixed price.

When charges are based on expenses, only the price per hour of work is established; the

fee is then calculated from the number of hours worked. This form of payment requires careful, continuous oversight.

When the unit price basis is used, a price is agreed on for each unit of performance. The total charge is the sum of these unit prices. This form of payment is suitable especially when changes and additions to the cost category are accepted. This billing system makes these particularly easy to handle. The amount of bookkeeping effort involved, however, is not inconsiderable.

The fixed price system calls for an exact description of the work to be done, largely completed plans, and installation conditions free of disruptions. The administrative cost is low. Changes in required installation may, however, lead to substantial cost overruns.

Engineering costs include all costs arising from

- Planning design activities
- Contract administration
- Supervision of installation work
- Start-up

In Germany, for example, engineering costs are largely set by the regulation governing architects' and engineers' fees [624].

Design costs are generally estimated on the basis of unit prices for stated functions. These activities can, however, vary in difficulty, and this fact is reflected in variable ratio factors. Some planning and design work, for example in the areas of feasibility study and project management, will be roughly equal in volume for any design project. This weighs more heavily on small projects than on large ones, so that small projects are more costly than large ones.

Contract administration and installation supervision are calculated on a percentage basis; commissioning is calculated in accordance with the man-hours required.

By way of example, Figure 320 (see next page) shows the cost structure of an investment for erecting a green-field chemical plant.

Cost estimates are made in parallel with the planning and design phase of a project. They become more accurate as the planning progresses.

The results of cost estimation form the basis for a profitability analysis and become part of the application for approval of the investment. Upon approval, the estimated costs become the binding cost framework for the project. Overruns are permitted only in a few justifiable (and exceptional) cases.

Adherence to the cost schedule requires continuous monitoring of costs over the project; an accounting of costs must be presented at the end of the project.

Schedule Management. In simple cases, scheduling can be carried out by using bar charts (Fig. 321, top), which show the beginning and duration of each activity as well as the earliest and latest occurrence of procedures along with buffer times. Such charts can be prepared at various levels of detail; if they are properly maintained, they provide a good overview of the schedule situation at any time. However, their critical disadvantage is that they do not show the interdependences between activities. For projects having a complex sequential structure, scheduling cannot be planned or overseen on this basis. Network charts can be of use in these cases [632].

In network charting, activities and relationships are stored in network files and graphically plotted, for example as shown in Figure 321, bottom. This technique makes it possible to determine not only the earliest possible but also the latest acceptable inception points for activities. Furthermore, if buffer times are analyzed, "critical paths" can be identified. A critical path is a path through the network that has no slack time.

Projects may contain more than one critical path, and these require especially close supervision during project execution. Schedule changes may open up new critical paths, but their influence on the overall schedule situation can be calculated in advance, allowing prompt reaction to such changes.

Network methods offer the project manager an aid in focusing on essentials in schedule supervision. The manager thus becomes free to perform other management tasks.

The charts used for this purpose must be continually updated. Because of the work involved in updating and the complexity that is sometimes associated with network charts, expecially in large projects, it is recommended that specially trained personnel be assigned to this job. A hierarchical procedure is also applied to network charts, where each decision maker is furnished with the requisite information structure.

Figure 320. Cost structure of a chemical plant investment

Petri networks (see Chap. 2) are the basis for all types of network charts.

Resource Management. Resource management (resource allocation) is an extension of schedule management [629], whereby "resources" are personnel, machinery, funds, etc.

In general, schedules are drawn up as if the needed resources were available in adequate quantity at any time; however, only rarely is this actually so. Generally, in-house and outside resources are limited. Resource shortfalls or the complete unavailability of resources will result in delays if, for example, certain activities must be carried out later or not at all, or if activities that should be performed in parallel and have been so scheduled, have to be carried out in sequence instead.

Such imponderables in scheduling can be avoided if scheduling and resource planning are combined. There are two approaches: resource-constrained allocation and resource leveling.

Resource-constrained allocation is based on what resources are available. Deviations from the original schedule are allowed, but the project duration must be made as short as possible.

Figure 321. Bar chart (Gantt chart) and network chart

In resource leveling, the specified completion date is the top priority and additional resources are procured to the extent required to achieve it.

In practice, an intermediate course is generally followed.

The resource "personnel" is often a cause of special concern. In boom times, for example, a resource leveling approach is questionable because not enough of the specialists needed for execution of a project may be available. One way out of this conflict, though it is seldom considered, is to reduce the originally stated scope of work. The prerequisites for doing so are that the quality of the work will not suffer and that retrofitting will be possible later on at no significant extra cost.

The problem of resource management becomes more complicated if several projects differing in structure must be planned at the same time, as often occurs in the chemical industry. The problem can often be solved only by assigning priorities to the projects (Fig. 322).

Figure 322. Resource management

Project activities are supported in a variety of ways by computer-aided management tools. These have been reviewed in [633] and [634].

The Microsoft project management system MS Project [635] appears to be finding acceptance in multiproject management situations.

Figure 323. Possible topics covered by feasibility study

10.3. Decision Phase

The fine structure of the decision phase can be seen in Figure 309. The purpose of the feasibility survey is to elucidate and develop the statement of tasks in close collaboration with the customer. Figure 323 shows possible points covered by a feasibility study for a chemical plant construction project.

The economic aspects are just as important as the chemical and process principles. These are supplemented by substance data and constraints. A detailed description of the plant completes the picture of the project. An additional analysis of weak points will reveal any flaws and thus contribute to making the task statement more concrete and precise (see Chapters 2, 3, 4).

This stage results in the performance specifications, which set forth the solution-invariant description of the problem to be solved (requirements). Its structure and content, in particular as it relates to plant safety, is discussed in more detail in Section 10.4.

In the preliminary design, a number of alternative solutions can be offered to the stated problem; from these, one is to be chosen as optimal for the company from both economic and technical standpoints (see Section 10.1), whereby a cost/benefit analysis may be useful.

Any optimization potential in the selected solution can then be revealed by sensitivity analysis, which investigates the influence of important, highly sensitive variables on the process by means of, for example:

- Mathematical models
- Application of empirical and theoretical knowledge
- Plausibility analysis

The optimization potential thus found can be realized in the design study. The result is a binding concept for both process and plant.

The binding concept is described in the specifications, whose structure and content are discussed further in Section 10.4, with particular regard to plant safety and economics.

The decision phase ends when the documents required for obtaining regulatory approval have been prepared and costing has been done (Section 10.2).

Errors in project planning and execution can arise from a wide variety of causes. The more serious are these problems and the later they are discoverd, they higher is the cost of correcting them.

10.4. Specifications

Bidding Specifications. The specifications describe the task in structured form, mainly from the user's viewpoint, and state what effort must be brought to bear [625, 636].

The bidding specifications can be regarded as the basis for a contract between the party designing and constructing the plant and the later plant operator. They are the basis of all further planning and design.

Structure and Content. The bidding specifications are broken down in parallel with the topics in the feasibility study (Fig. 323). They are broken down into a general section relating to all components and a specific section for each component (Fig. 324).

Figure 324. Breakdown of bidding specifications

The general section includes important information applicable to all components. Possible topics in the general section of the bidding specifications are:

1) General information on the project
2) Current position and shortcomings
3) Objective
4) Structure of the process and plant
5) Safety and availability requirements
6) Miscellaneous conditions to be considered
7) Framework concept

A vital part of the general section of the bidding specifications is the "framework concept," which describes the real environment of the plant as well as expected expansions. This section, in particular, describes interfaces to other plants (not just for process measurement and control).

The component sections of the specifications discuss these points only briefly, or may simply refer to the general section. Instead, these sections state the points of importance for the execution of the particular tasks. Possible contents of the section on process measurement and control are:

1) Typical requirements for process control station functions
2) Special control and monitoring functions
3) Process control functions
4) Human/process communications
5) Off-line interpretation functions
6) Infrastructure; room and building equipment
7) Communications hardware
8) Process analysis
9) Safety requirements
10) Availability requirements
11) Quality assurance
12) Miscellaneous

An important item in the bidding specifications is the description of functions used to control the process. The particulars of process measurement and control are described (Fig. 325, column 3) [637].

"Field-level" functions for the performance of control and safety tasks are distinguished from "higher-level" functions involved in the management of the process and the plant. The later include, for example, process operation, process logistics, and recipe-mode operation (Chaps. 2 and 4).

These functions in turn are interfaced to other higher-level functions involved in the management of a works/plant complex or corporate management (Fig. 325, columns 1 and 2) [637].

The breakdown of functions is based on the level model of production (Fig. 326) [638] (see also Chap. 2).

The totality of functions to be performed and their interfaces to one another defines the type and size of the process control systems. For example, Figure 327 shows a system that handles the functions of all levels of the production model (see also Section 5.2).

The holistic view and conceptual procedure require prompt acquisition of information about necessary and desired functions for the later operation of the plant. Particulars of various process management tasks are treated in depth in Section 4.3.

Corporate management	Plant management	Process management

Rough cost estimation	

Figure 329. Structure and content of specifications

The rules stated in Chapter 2 apply in a special way to the description of recipe-mode operation [636, 639] (see Fig. 328), [640, 641].

As proposed earlier [636], the bidding specifications are now prepared in checklist form [642].

Process engineering functions may also include room and building functions (heating, climate control, ventilation, lighting, etc.) as well as communications (e.g., telephone).

Specifications. The specifications give a detailed description of the nominal condition, that is, how and with the requirements of the bidding specifications are to be realized. The specifications set forth the solution-variant realization. These documents are binding on the contractor (in-house planning and design department or outside firm). The specifications form the basis for the contract, especially when the planning and design work is contracted out [625].

Structure and Content. The specifications are organized similarly to the bidding specifications and consist of a general section and component-specific sections.

The process-engineering aspects governed by the specifications are illustrated in Figure 329. For the sake of comparison, provisions for the process and for the plant are listed in parallel [631, 643, 644].

Provisions on process and plant are first briefly explained (left column of Fig. 329).

The structuring of the process and of the plant is the same as set forth in the bidding specifications (see also "Phase Model of Production" in Chapter 2, as well as Figs. 330, 331, 332). The breakdown is taken over into the specifications unless changes have been made; otherwise, it is modified to accord with the new requirements.

The breakdown of the process is independent of whether it is already known or new within the company.

Even known processes must be restructured since a new investment always entails adaptation to the state of the art, and adaptation can strongly affect the process structure.

According to [645], the process can be broken down into process stages and unit operations. Some concepts in [645] must be modified, because there is no guarantee of completeness, uniqueness, or freedom from conflicts. "Process stages" are generally self-contained portions of a process.

Unit operations are the smallest steps in a process and correspond to process elements. Any unit operation converts inlet products with par-

ticular properties to outlet products with different product properties. As was discussed in Chapter 2, product properties are those qualities that characterize the product, such as physical and chemical values, engineering properties, and product indicators [236, 646].

Figure 330. Extract from a phase model

Figure 331. Example of a list of product properties

A unit operation can be specified as shown in, for example, Figure 24. It can be specified, for example, that a separation is to be carried out by distillation. Such a statement of the method of performance also establishes the basic form of the trajectories that describe the transformation of inlet products with their properties into outlet products with theirs. The properties that characterize this transformation process are the process properties.

Figure 330 shows a unit operation with the inlet and outlet products, their product properties, and the process properties. The product and process properties must be set forth in the specifications for the process. As Figure 331 shows, the acceptable ranges of variation (tolerances) should also be given if possible. In this way, a profile of requirements on the overall process is obtained; this should cover all operating modes (startup, shutdown, load change, etc.; see Fig. 332). This description, coupled with actual values, is the basis for a quality information system (QIS).

The profile of requirements is the essential condition for creating a reproducible operation [625]. The overall sensor and actuator system is later defined and quantified on the basis of this profile. Further more, possible ciritcal states of product properties, which might affect the availability of the sensor – actuator system, can be identified in this way (plugging due to solid/liquid phase separation, etc.).

Material and thermal balances indicate ways of insuring the supply of substances and energy to the process and the removal of substances and energy from it. They also give the consumption rates per unit amount of product, which are required for the profitability calculation at the end of the decision phase (Section 10.4).

Once the process structure has been completed, the plant structure is broken down by assigning unit operations to appropriate plant sections. A plant section is a functional unit of a plant that can be operated independently (corresponding to a unit operation). Examples of plant sections in chemical process plants are absorbers, chemical reactors, crystallizers, tank storage facilities, and so forth.

The totality of all plant sections required for the performance of a process is the plant.

Technical equipment in a plant section includes both devices involved in the process, such as vessels, machinery, apparatus, piping, and fittings, and process measurement and control units [647]. The detailed description of a plant section is based on these elements (see Fig. 23).

Safety and economic considerations result in a variety of requirements being imposed on the

Figure 332. Property profile of an overall process [646]

objects of a plant, such as plant sections and technical equipment. Such requirements must be taken into account in planning and design, construction, and operation.

In the lifetime of a plant, a large quantity of data is generated, used, interchanged, and if necessary modified. If such data and other information is to be exchanged without losses, each item of information must be uniquely associated with the plant object to which it relates. This can only be achieved if the objects are uniquely labeled [648].

Plants and apparatus can be identified in various ways. For example, each can be assigned an unstructured designation.

In a complex system such as a chemical plant, it is better to structure the system in a hierarchical fashion, and then have the system of identification codes reflect this structure. In this way, an informative and easy-to-use identification of plant objects is obtained [649, 650].

An engineering object can be "named" in many ways; a few examples are: by purpose, by technical function, by location, or by device type.

If all such features were included at once in the object identification, an unwieldy code would result. For this reason, just a single attribute is employed. It is desirable to choose a feature that is completely and permanently identifies the object (e.g., the technical function [203]). This can be illustrated for a temperature measurement and control station.

Suppose the purpose of the station is to maintain a constant temperature in a certain unit operation, say mixing. The technical function is to

measure, record, indicate, and control (TIRC) at a certain point in the plant, a Pt 100 instrument being used as the measuring sensor.

If this sensor is now replaced by a thermocouple or if the plant is changed over to a different process with different unit operations (e.g., reaction instead of mixing), the station still retains its technical function.

The coding of technical objects is a planning/design task. It is carried out as early as possible, but at the latest when the specifications are prepared. This is done in entity – relationship (E/R) models, which are generated in a consistent way throughout the company.

On the basis of the safety provisions in the bidding specifications, the safety concept is derived from the operating conditions together with the potential hazard presented to persons and the environment by substances involved in the process.

A construction concept and a provisional identification of the site round off the process and plant concept.

The overall concept is documented in phase models plus the overall and process flowsheets discussed in Chapter 2, which contain fundamental and supplemental information.

The process measurement and control concept follows from the process and plant structure, the profile of requirements on the process, and the task statement contained in the bidding specifications.

The specifications set forth the types of process measurement and control stations and, roughly, the way in which they are interconnected.

The process and plant control functions performed by the control system determine the extent to which the plant is automated (see Section 4.3).

If functions on the plant control level are also to be implemented, a production control computer must be provided. The interfaces between functions at different levels must be described and specified as exactly as possible (see Chap. 2).

The number of field-level components and their assignment to plant sections is based on the process structure, the required functionalities, and the safety and availability requirements.

The operation and monitoring concept (see Section 11.2) essentially comprises the specification of operator displays, reports, and logs. The operator station concepts must also be worked out. These define the scope of tasks to be performed at the various control stations and the association of control stations with plants and plant sections [651].

The information structure should be hierarchical, with high-level diagrams containing few items of information, and station-level diagrams, extensive information.

Reports should be specified and classified as follows:

- Alarms
- Malfunctions (in the measurement and control system)
- Warnings (advance notice of alarms)
- Errors (in the peripheral hardware of the measurement and control system)

Safety and availability requirements govern how priorities are to be assigned to the messages and how they are to be presented in the control system (see also "Availability Aspects" below).

Logs and records are subdivided into, for example, batch records, shift logs, daily logs, and alarm logs.

If, for example, the bidding specifications call for recipe-mode operation, the software specifications (Fig. 329) should include the appropriate large-scale function charts, specify the selectable parameters of the recipes, and state how the recipes will be maintained and archived.

At this point, the task to be performed has been explained enough that a concrete solution proposal can be submitted with the aid of a process control system. This proposal must, however, take account of the measurement and control provisions described in the framework concept of the operation in which the process will be realized. For example, if a process control system from a certain manufacturer is already in use, then for maintenance reasons it is recommended that the planner stay with this manufacturer unless the adaptation to the task carries unacceptable risks with it.

Availability Aspects. *Basic Classification of Process Measurement and Control Equipment.* Availability requirements must be examined from several viewpoints:

- Safety
- Process engineering

– Logistics

Safety is mandated by legislation and regulations. The safety of persons in the plant (worker protection) and of the surroundings (environmental protection) must be guaranteed.

The safety of engineering processes is a key criterion. A high level of safety results from continual and intensive work on safety aspects. Once a high degree of safety has been achieved, it must be maintained and improved. The special handling of safety aspects in the bidding specifications and the specifications is meant to stress this requirement.

The term "process" is understood to mean the totality of interacting operations in a system by which matter, energy, or information is transformed, transported, or stored. In the case of technical processes, the physical quantities are determined and controlled by technical means [652].

The safety of a process is determined by the processes, plants, and process control equipment (Fig. 333). An essential contribution to process safety is due to process control equipment [653]. Such equipment can be classified as shown in Figure 333.

Figure 333. Summary of measurement and control equipment performing process safety functions

In assessing process safety, the following three types of operational conditions are distinguished [653]:

– Good range
– Acceptable range
– Unacceptable range

The good range is the intended range for the values of a process parameter. It is defined such that the plant does not sustain any damage beyond ordinary wear and tear, while the quality and quantity of goods produced satisfy the requirements imposed.

The acceptable range is adjacent to the good range. In it, the plant still sustains no damage beyond ordinary wear and tear; the quality and quantity of goods produced still satisfy the requirements to within extended tolerances.

In the unacceptable range, the value of a process parameter is such that the plant may sustain or cause greater damage, or the quality and quantity of goods produced no longer satisfy the requirements stated.

These parameter ranges can now be correlated with process measurement and control equipment. Devices used for measurement, control, reporting, and so forth serve to keep the plants operating as intended (in the good range). They continually intervene in the process. Only in the acceptable range do the process control safety devices first come into operation. On entry into this range, the monitoring devices respond, prompting the operator to take suitable action to bring the process back into the good range.

If these actions are not taken as expected, protective features in the process measurement and control system, such as safety valves, rupture disks, and the like, prevent entry into the unacceptable range.

Processes can further be provided with damage-limitation features such as spray-blocking walls, warning systems, and special traffic control systems that block off the site of the danger.

Figure 334 summarizes the correlation between the ranges of process parameters and the process measurement and control devices, showing the intervention levels and modes of action [653].

The safety requirements mandated by legislation for the overall process in a plant to be erected, and in particular for the process control equipment, must be precisely described in the bidding specifications, since they influence the process design as well as the design of the process measurement and control system.

The required availability from the process engineering standpoint affects both product quality and the protection of the facilities. The logistics-

Figure 334. Process control devices and process safety [653]

based availability bears on the ability to deliver products and has direct effects on manufacturing costs. The availability requirements imposed by logistics and process engineering must be included in the economic picture, in contrast to the safety requirements.

The measures taken to comply with these requirements are set forth in the specifications.

Implementation. The safety and availability requirements are key factors affecting the structure and organization of field-level and system-level components. These lead to, among others, the need for the process sections and/or plant sections to be largely autonomous relative to one another and relative to malfunctions in higher-level operating and/or control computers.

To insure the protection of workers and the environment as mandated by law, a number of other technical measures set forth in codes and regulations must also be undertaken. A few of these are listed in Figure 345.

Allowance must always be made for defects that limit the proper functioning of technical equipment or even take it out of action. In the case of safety equipment, care must therefore be taken that no impairment or failure of the safety function occurs even when there are defects in the technical equipment performing such safety function.

This goal can be achieved through two distinct approaches to safety equipment design, called "fail-safe" and "redundant." In fail-safe design, all malfunctions deemed possible cause the safety devices to fail in a single well-defined sense, namely so as to trigger the safety or protective function. Redundant design means including more than one component for a certain task. If one component fails, a backup component takes over its function.

Redundancy in process control systems means that system components, such as field-level, operating and monitoring units, and/or bus systems, are present two or more times. The types of redundancy practiced in technical systems are as follows [654]:

Static redundancy. Instead of a single component, several components are installed in parallel. The system as a whole performs in the intended way as long as at least one unit is free of defects.

Dynamic backup redundancy. In case of malfunction, an additional component is switched in to replace the defective component. The additional component is not in operation when no malfunction is present.

Local dynamic backup redundnacy. Assigned to every component is a redundant compo-

nent, which is continuously reconfigured (hot standby).

Global dynamic backup redundancy. A redundant component is assigned to several components. In case of a malfunction, the redundant component is reconfigured once (warm standby).

Dynamic functional redundancy. When no malfunction is present, the redundant component performs its own tasks; if a malfunction occurs, it takes over the functions of the defective unit by restricting the capacity or shutting down inessential functions.

Backup. The general term "backup" refers to dynamic backup redundancy for a single process measurement and control function, such as control.

There are a variety of methods for acquiring redundant information about the process. Figure 335 presents some typical examples.

Figure 335. Redundancy in measurement [653]

The term homogeneous redundancy is used when the same physical quantities and the same measurement techniques are empolyed for data acquisition. Physical diversity uses distinct physical quantities. Methodological diversity means using the same physical quantity for data acquisition, but measuring it by different methods.

In process measurement and control systems, functions are implemented through hardware and software. Process control systems should be used to realize safety devices only when they can be validated, that is, when it can be demonstrated that the software involved in the safety function always performs properly and reliably under all circumstances. If this cannot be demonstrated, safety functions must be implemented by hardwired control units.

Redundancy implies a high-availability concept. Despite, or indeed precisely because of, the presence of multiple process components, such high availability is not always realized. Problems arising from the number, interconnection, and synchronization of components in a redundant system may work against it.

Safety concepts and availability requirements must also affect the security of the process power supply system. The number and type of incoming supply lines, multibus configurations, switching devices, and standby power systems depend on it [655]. Section 6.4 surveys the most important options.

The specifications contain additional provisions dealing with the infrastructure (Fig. 329), including process control areas, such as control and switching rooms, as well as overall building equipment.

The specifications end by giving cost figures and the profitability calculations based on them. These are crucial for the decision to continue with the investment project. If the economic criteria established by corporate management are satisfied, the project is continued; otherwise, either its scope is modified or its is terminated.

Economic Aspects. The purpose of any investment project is to generate profits. The specifications must therefore demonstrate that the proposed actions to carry out the tasks described in the bidding specifications will contribute to profits. The question of economics is vital, especially with regard to the desired level of automation (Section 4.3)

[625]. A separate economic calculation can be done for each automation level.

– Automation of field-level functions of the process control level (Fig. 325)

This level is mainly concerned with the functions of measurement, control, operation, and reporting. These can be implemented by conventional method or by process control systems. An analysis of several projects has shown that there is, in principle, no difference in financial outlay between these two options. Both investment costs and the breakdown of costs (Fig. 336)

Figure 336. Comparison of cost breakdowns for the implementation of field-level functions of the process control levels with conventional process control technology and with process control systems [637]

are roughly comparable. On the basis of this knowledge, control tasks of the type discussed here should always be implemented with process control systems, since these have potential for expansion that is generally lacking with conventional methods.

– Automation of field-level and higher-level functions of the process control level

As Figure 325 shows, process control systems make it possible to carry out recipe-mode operation, tasks having to do with process logistics, and higher-level control functions. The automation of packaging lines or storage facilities can be included under this heading.

Performing these functions generally entails additional investment costs, which are, however, justified only if the annual profit gained through their use exceeds a certain value specified in advance by corporate management. The profit is calculated as the savings achieved through the investment minus fixed costs.

The profit expressed as a percentage of the total investment is called the return on investment (ROI).

$$\mathrm{ROI}\,[\%/\mathrm{a}] = \frac{\mathrm{savings}\,[\mathrm{DM/a}] - [\mathrm{fixedcosts}\,[\mathrm{DM/a}]]}{\mathrm{totalinvestment}\,[\mathrm{DM}]} \times 100$$

The reciprocal 100/ROI is the payback time, i.e., after how many years the total investment is paid back in profits:

Either figure can be used as a rough measure of the profitability of an action.

Table 12 shows a cost analysis done in this way. The benefits can be broken down in a variety of ways, but essentially into five categories,

Table 12. Cost analysis for the implementation of higher-level functions at the process control level using process measurement and control systems [656]

Task	No. of projects	Savings ∗, 10^3 €/a							Total investment, 10^3 €	Fixed costs, 10^3 €/a	ROI ∗∗, %/a
		Improved product quality	Reduced inspection	Energy savings	Personnel savings	Improved yield	Enhanced plant utilization	Sum			
Recipe-mode operation	2	–	+	–	232	–	197	429	665	146	40
		38	+	–	332	255	105	695	971	192	50
Process logistics	1	+	+	+	204	613	+	818	1278	304	40
Higher-level control technology	1	+	–	82	112	–	–	194	276	74	40
Automated packing/storage	2	+	–	–	+	–	+	245	232	59	80
								2086	1227	297	140

∗ + Beneficial but not quantifiable; – No benefits identifiable.
∗∗ Return on investment.

although not all of these can be quantified. If only the quantifiable items are included, satisfactorily high ROI values or satisfactorily short payback times (all < 2.5 years) are obtained.

These results favor the use of process measurement and control systems for the implementation of higher-level functions of the process control level.

– Automation of functions of the production control levels (Figs. 325 and 326)

The economic analysis is problematic because the simple investment return calculation methods described above are no longer adequate. The associated benefits of better information (i.e., comprehensive, up-to-the-minute, error-free, and perhaps condensed) being available as the basis for analyzing both engineering and management weak points and also for the real-time control of the operation cannot be quantified.

Ultimately, corporate objectives will dictate the implementation of a production control level. Failure to do so, however, may result in long-term competitive disadvantages.

10.5. Execution Phase

The fine structure of the execution phase is indicated in Figure 309

Basic Engineering. In the basic engineering phase, the individual tasks are formulated in their final form, in collaboration with the customer, and the functional solution is described. The work to be done here is listed below:

Planning and design for process and plant engineering:

– Design of plant sections (apparatus) in accordance with the process
– Decision on materials of contruction
– Preparation of site plans and provisional layouts
– Preparation of piping and instrumentation diagrams

Planning and design for process control engineering:

– Design of process control stations
  Establishment of structure
  Establishment of devices to be used
– Design of process measurement and control system
  Dimensioning of process interface
  Design of data processing software
  Dimensioning of the control system
  Dimensioning of control and other rooms
  Spatial disposition in the plant
– Preparation of piping and instrumentation diagrams

The process and plant engineering work includes plant design in accordance with the process, sizing of the plant sections (apparatus), and elucidation of materials questions. With regard to documentation, see in particular Section 3.5.

Preparation of Piping and Instrumentation Diagrams. A key task is the preparation of P & I (piping and instrumentation) flowsheets [645] (see Fig. 337). Provisional layouts and site plans are also drawn up.

The process control engineering organization is involved in the preparation of P & I diagrams, since its planning and design work will be based on these. Process control tasks are described in the station symbols (Fig. 338) of the P & I diagrams. This description should be sufficiently exact enough that it, together with the binding concept, makes possible the design of the PCE stations.

The process control station includes all measurement and control elements needed to perform the functions specified, such as sensors and/or actuators, signal transducers, power supplies, and processing functions, for example indicating (I), recording (R), controlling (C), etc. [657].

Process Control Station Data Sheet. The station design is set forth in a "data sheet," which must list all elements making up the station and also provide information on the substances with which the sensors and actuators come in contact and on the installation location (Fig. 339).

Given the measurement and control ranges of the sensors and actuators, suitable equipment is identified for the individual elements on the basis of instrument standards (see Chaps. 7 and 8 and Section 10.6).

Process Control Station Diagram. Station diagrams document how the equipment is wired together (Fig. 340). At this point, the planning and design work on stations utilizing conven-

Figure 337. P & I flowsheet of a plant

tional technology is finished. If data processing functions are implemented in process measurement and control systems, additional design work is required for the hardware structure of the process interface as well as the software structure incorporated into the control system proper.

Figure 338. Representation of a process control station in the P & I flowsheet [647]

Analog and binary signals coming into the process control system must be transformed into information that this system can understand. The conversion takes place in the process interface and is performed by input/output components for the various types of signal. Backup controllers are also implemented with components. These components are shown in the station data sheet as well as the station hardware diagram (Fig. 341; see also Sections 7.2 and 10.2).

Station Software Diagram. The station hardware diagrams are supplemented by station software diagrams (Fig. 342; see also Section 9.6), which show how standard software modules, provided by the process control system manufacturer, are linked so as to build up the PCE station processing functions.

Function Chart. The data processing functions of a station must be performed in a coordinated manner; this requires a coordination function at a higher level in the hierarchy. The essence of this function is a task-specific sequence control that must be specially prepared for each field-level component of a measurement and control system. Sequence controls are formulated in a system-neutral way by using function charts (Fig. 343) [658]; the same holds for station-level interlocks.

The function chart is a process-oriented depiction of the control function, independent of the way in which it is implemented. It replaces or supplements the verbal description of the function. The function chart clearly and unambiguously describes the function and thus aids in understanding between manufacturer and user. Furthermore, it facilitates collaboration between specialists [659]. In future projects, Petri networks will be employed at an early stage, from which function charts can be automatically generated (see Chap. 2 and Section 4.3).

Figure 339. Example of a station data sheet

Figure 340. Example of a station plan for a conventional process control station

Dimensioning of Process Measurement and Control Components. Generally, a process measurement and control system consists of a number of field-level components. Like the station-level functions of field-level components, these must also be coordinated, but at a higher level, for example, in the context of recipe-mode operation. A process control computer is used for this coordination function.

The size and type of control computer will depend on the scope of the coordination function. The selection of the operating computer is based on the number of graphical operating displays (Section 11.2).

The number and size of the field-level components assigned to a process section is influenced by the number of stations to be implemented, the functional scope, and the requirements on availability and safety (Section 10.4).

Figure 341. Example of a hardware station diagram for a station with signal processing (LS+)

Figure 342. Example of a station software diagram for a station with signal processing (LS+) in a process measurement and control system

The station-level functions are built up from software modules. These differ in memory requirement and machine time, so that flow-through and pressure-control loops assembled from such modules may require 3 – 4 times as much memory and 4 – 6 times as much processing time as pure measurement loops.

If a large number of time-comsuming functions must be implemented in a single section of the process, field-level components whose time properties allow this must be used. Today, memory problems are of little importance.

The tasks of basic engineering also include dimensioning the rooms for the installation of process measurement and control equipment (see Section 10.7).

Detail Engineering. In the detail engineering phase, detailed and comprehensive documents are prepared for use in procurement, construction, operation, and maintenance of a plant. Consistent documentation is a vital consideration at this stage (see Section 3.5). The planning and design work can be broken down between process and plant engineering and process control as follows:

Planning and design for process and plant engineering
- Detailed layout of plant sections, apparatus
- Construction drawings
- Site plans, layouts
- Piping design

Planning and design for process control engineering
- Preparation of data sheets
- Completion of station diagrams and function charts
- Programming
- Working drawings of mimic diagrams for operation and monitoring
- Preparation of circuit and configuration diagrams
- Preparation of commissioning checklists

Figure 343. Example of a function chart for tank filling

Preparation of operating handbook
- Preparation for letting contract to outside firms
- Orders and contracts
- Scheduling and resource allocation for installation

The plant design activity prepares design drawings for machinery and apparatus. Construction design supplies building plans as well as calculations of foundations, floor loads, vibrational loads due to machinery, and so forth.

The piping activity supplements its design documents with piping isometrics and parts lists. Care should be taken here to achieve smooth cooperation with local field instrumentation and cable routing activities (e.g., with the aid of suitable 3 D CAE methods).

Planning and design of the process measurement and control system completes the documentation generated in the detail engineering phase.

The PCE station hardware diagrams contain additional information making it possible to localize the station elements by giving, for example, the switchbox identification, rack-mount module number, card slot, and also to identify the incoming and outgoing signal lines by referring to the terminal numbers. Figure 344 shows a detail of the station diagram of Figure 340 with this supplementary information.

Figure 344. Excerpt from a supplemented station diagram

The station software diagrams, function charts, designs for recipe-mode control operations, and other higher functionalities are transformed into programs understandable by the process control system.

Because screen displays are associated with variables in the software modules, the preparation of screens for process monitoring and control is an expensive process. It can account for a substantial fraction of software costs. Before this step is performed, the screen must be designed. A useful tool for the process of agreement with the later operator of the plant is working drawings, usually prepared by CAD methods, which are easy to change and supplement. Special ergonomic requirements for state-oriented operation are discussed in Section 8.2.

An operating handbook must be written during detail engineering. It should assist in the early detection of design errors and the taking of proper corrective actions. Design errors can be remedied in a relatively cost-neutral way at this point. Corrections upon commissioning are expensive. Unfortunately, little use is made of this capability at present.

The following activities are carried out in collaboration with the purchasing departments:

- Requests for quotations to vendors and/or installation firms
- Orders

When contracting with outside firms, the nature and content of the contracts are agreed on with the legal and purchasing departments.

For installation, schedules should be prepared with allowance for delivery times (see also the network chart in Fig. 345).

It is also desirable to generate a commissioning concept, which should use diagrams and lists to document the following points (among others):

1) Personnel requirement
2) Schedule
3) Procedures
4) Type of functional tests, etc.

More and more computer-aided tools are used as planning and design aids. These support not so much the conceptual phase as the manual or material phase of design, where the plans needed for the erection and operation of the plant are drawn up (see Chap. 9).

Installation. Installation includes the erection of all classes of equipment involved in an investment project and the interconnection of all components into a completed, operational plant. The stages in installation are as follows [631]:

Preparation
Site preparation
Site organization

Execution
Steel construction
Installation of machinery, apparatus, tanks, etc.
Installation of piping
Installation of process measurement and control equipment
Installation in process control rooms
Installation of cable trays in the field
Field installation

Inspection
Machinery, apparatus, tanks
Operability
Tightness
⋮
Process measurement and control
Visual inspection
Wiring inspection
Functional testing

The preparations include the contruction of a site with site offices, storage areas, and installation areas, as well as the creation of a site organization to handle scheduling, resource allocation, costing, and the monitoring of performance relative to these plans.

Good installation planning reveals itself in that the installation of individual categories of assets is coordinated so as to insure smooth, reliable progress. Interferences between categories should not occur. What is more, all resources – such as installation personnel, plant sections, components, and other materials required for the installation of individual asset categories – and all working plans and related documents should be available on time and in adequate quantities and should meet stated quality standards.

The on-schedule installation of process measurement and control equipment requires special care, since as a rule it cannot be started until significant parts of the other categories have been installed. Detailed network charts (see above) can be helpful here.

The installation of process measurement and control equipment falls into three parts:

– Installation in control rooms
– Installation of cable trays in the field
– Installation of process measurement and control devices in the field

Installation "in the field" means all installation activities outside the process control rooms.

Installation work in the control rooms can begin at a very early time in the overall installation process, immediately after the buildings have been completed. Some 20 % of all process control installation work falls under this heading. Cable tray installation can proceed roughly in parallel with piping installation. But the installation of instruments cannot start until ca. 80 % of the piping installation has been done.

Installation ends with an inspection, which is part of the quality assurance (see Section 10.6).

The installation activity must be thoroughly cognizant of the "concurrence" of events in the sense of Petri network theory (see Chap. 2).

Installation offers a broad range of rationalization possibilities for later maintenance practices (see Section 11.4). The equipment manufacturers still have some way to go here (see Section 11.1).

Figure 345. Information flow and process control engineering documentation in the basic and detail engineering phases [631]

10.6. Quality Assurance

The quality of the items prepared must be continuously assured during the project. These include plans, software specifications, programs, plant sections, installation, and so forth. Consistent documentation must be provided for all these activities (Section 3.5, [660,661]).

Major elements of quality assurance are

- Provisions governing planning, design, and installation
- Controls

– Inspection and testing

Today, inspection and testing includes data-model-oriented consistency checks, as known from software engineering, as well as final installation inspection and commissioning.

Governing provisions are, for example, legislation, standards, and internal corporate directives.

Legislative provisions describe the constraints under which a plant is to be erected and operated. They safeguard the environment, in the broadest sense, against possible threats (see Fig. 345).

In addition to legislation, a number of national, regional, and international standards must be considered. These standards essentially serve to ensure consistent planning, design, and execution (see also Chap. 12).

Internal corporate guidelines interpret and give concrete form to the provisions of laws and standards as well as corporate objectives (see Fig. 10).

Examples of provisions for process control engineering are given below:

General planning/design guidelines
– Documentation
– Nomenclature, identifications, abbreviations

⋮

Provisions governing project planning and execution
– Description of scope of work
– Costs; ordering
– Schedules
– ⋮

Substance data
Basis for calculations and design
Technical provisions
– Interconnection of devices
– Protective, safety, reporting systems
– Hardware and software structure of control systems
– Outfitting of process control rooms
– Equipment for building, labs, shops

⋮

Provisions for fabrication and installation
– Design of standard modules
– Design of protective enclosures, distribution boxes, instrument housings

⋮

"Design standard" is understood here to mean technical provisions for the function "planning and design." The design standard for process control engineering is supplemented by an equipment standard, which narrows the range of devices available on the market to a few choices, in particular those that have proved reliable in many years' service or through qualification tests (see Fig. 10).

The scope of work often goes through marked changes in the planning and design of a plant. The reason is inadequate preparation of the investment project. The nature and quantity of the technology to be implemented are not described exactly. Concepts change later on, and designs already adopted must be reworked. The resulting "patchwork" can hardly improve quality and, as a rule, actually degrades it.

Situations of this kind cannot be avoided, but proper preparation of the bidding specifications and specifications can significantly improve them. They must therefore be regarded as an important contribution to improving the quality of planning and design.

Design quality control is a major undertaking, because of the large volume of documents generated. It becomes more difficult if the design work is done by outside firms. For this reason, quality control is often reduced to just a spot-check of results. An object-oriented data model for the plant as a whole is thus all the more important (see Section 3.5 and Chap. 9).

It is shown below for the example of the hardware documentation of a process control engineering project that this procedure is quite adequate for practical use. A differentiated assessment of process control engineering documentation requires breaking it down into units for examination. In the case of hardware documentation, the logical unit is the documentation of a single process control station, comprising the station data sheet, the station diagram, and the corresponding information from the interconnection lists. These documents can be examined as soon as the execution planning has been completed; if the complete job (planning, design, installation supervision, and commissioning) is carried out by one contractor, they can be inspected after the process facility has been commissioned. In the case of a complete contract,

the contractor therefore has to examine the documentation only once.

For the documentation of a process control station to be deemed correct after commissioning, the documents included must meet all the following quality criteria:

- The station identification must be correct
- The documentation must correctly reflect the equipment installed
- Any cross-references required must be present
- Each terminal designation must be correct; that is, the information in the process control station diagram and in the associated interconnection lists must agree with the actual interconnection of the devices

The results of two sampling inspections of process control engineering documentation for a project comprising 324 PCE stations are shown in Figure 346. In the first examination, the sample size was increased in steps of 32 PCE stations (roughly 10 % of the total number of stations). Above a relative sample size of ca. 30 %, the relative error is nearly constant, and it appeared unnecessary to continue the inspection in this case.

Figure 346. Quality inspection of process control engineering documentation of a project comprising 324 process control stations

In a second inspection by a different inspector, only those errors overlooked in the first inspection were noted. The result is around 5 % and must be regarded as the errors of the first inspector ("slip-through"). Similar slip-through values were found in studies of the manufacturing industries [662].

The results of this examination show that inspection of the process control engineering documentation by the contractor is essential [663]. In practice, the following procedure has proven suitable: If the customer's examination reveals an error lying above a predetermined threshold (e.g., 5 %), the customer returns the entire documentation to the contractor for complete revision. However, if the relative error is < 5 %, the contractor need only remedy the errors found [664].

On economic grounds, only spot checks can be carried out on the process control engineering documentation. Therefore, the risk exists that the error found in the spot check is greater (risk for contractor) or less (risk for customer) than the "true" error that would be found in a complete examination. To resolve this conflict, model calculations have been performed in order to determine the sample size for various project sizes (number of process control stations). The following assumptions were made:

- The error limit for acceptance of process control engineering documentation is 5 %
- The sample must be large enough that the probability of accepting the documentation (contractor's risk) when the documentation contains a relative error > 10 % (twice the acceptable error limit) is < 20 %
- The "hypergeometric distribution" is the appropriate mathematical description of the sampling inspection described [665]

The results of these model calculations are presented in Table 13. The most important result of these model calculations is that in projects with > 100 process control stations, given an acceptable limiting error rate of 5 %, sampling inspection of 50 stations is sufficient to decide on the acceptance of the process control engineering documentation or assurance measures. The advantages of sampling inspection in large projects are greatly reduced insepction costs.

Table 13. Sample size for quality inspection of process control engineering documentation

Number of	Sample size	
PCE stations	Absolute	Relative
20	14	70 %
50	35	66 %
100	50	50 %
500	50	10 %
1000	50	5 %

The monitoring of software design presents major problems. In principle, software design can be checked only during commissioning. A modular architecture is helpful if it permits step-by-step testing, from the single module up to the entire system. This type of examination cannot, however, eliminate software defects that lie outside the scope of the check. Software always hides certain imponderables; hence the recommendation that functions of immediate safety significance never be performed by software alone, but always in combination with a conventional safety level (Section 10.4 and [653]).

It can be expected that the quality of planning and design results will improve markedly if the computer methods still in development (see Chap. 9) are adopted.

Quality assurance also requires installation practices such as the following:

- Issuance of installation standards (technical provisions for the function "installation")
- Incoming inspection
- Supervision of installation activities
- Functional tests

An example for the contents of an installation standard for process measurement and control equipment is listed below:

Provisions on the mechanical construction of process measurement and control equipment in control rooms and other rooms
- Panel designs
- Cabinet and rack-mount designs
- Subracks
- Cooling air supply and distribution
- Cable basements
- Cable lead-throughs
- Cable trays and their routing on pipe bridges
- Distribution boxes
- Transducer boxes design and installation
- Terminal boxes

Provisions on electrical design
- Auxiliary power supply
- Grounding/equipotential bonding
- Cable routing
- Power supply and distribution
- Hookup methods

Provisions on the construction of process measurement and control stations

Installation material in configuration and interconnection

⋮

It contains, for example, provisions on
- The mechanical construction of process measurement and control equipment in control rooms and other rooms
- Electrical design
- The construction of individual stations

These standards should be supplemented by installation layout diagrams (Fig. 347), which use drawings and lists to set forth the installation materials needed for certain tasks as well as their configuration and interconnection.

No.	Pos.	Name	Amount	Data sheet	Material
1	44	Hose-pipe coupling, triple	1	7.5 Bl. 1	Polymer
2	51	Cylinder-head screws R 1/4" × 12	1	7.5 Bl. 1	Polymer
3	81	Compression gland PG 13.5	1	6.9 Bl. 1	plastic
4	83	Compression gland PG 21	1	6.9 Bl. 1	plastic
5	100	Pressure transmission cable, 3 tubes, Type D2YBY	20 m	7.1 Bl. 1	
6	104	Wire NYM-I 5 × 1.5	20 m	6.3 Bl. 1

13	199	Mount for pneumatic terminal box	1		steel
14	200	Mount for electrical terminal box	1		steel

Figure 347. Example of an installation configuration plan [631]

The quality of an installation activity is also enhanced if standardized, prefabricated, and pretested hardware components and other equipment are employed.

In process control engineering, the use of such standard elements in the form of panels, racks, cabinets, cable trays, subracks for alarm devices, power-supply equipment, and so forth has long been common.

Incoming inspections during installation relate not only to the work plans but also to the materials and equipment to be used. The plans must be complete and correct; materials and devices must comply with specifications.

It is desirable to have specialist personnel – for example, project engineers with knowledge of the process or installation foremen with competence in the work to be done – to supervise the installation activities. Such personnel should be designated by the customer of the project. Only in this way can high-quality execution be guaranteed.

An essential element of quality assurance is the final installation inspection (see "Installation" in Section 10.5, and [631]).

The process control engineering activity carries out three levels of inspections:

1) Visual inspection
2) Wiring checks
3) Functional testing

This procedure insures that the individual process measurement and control devices perform correctly and interact properly.

Visual inspection establishes correct mounting. Proper interconnection of the elements is determined by wiring checks.

The aim of functional testing is to ensure that the active operating sequences of the process measurement and control devices accomplish the functions specified for the process tasks. On the basis of the planning and design documents, the individual process control stations are systematically inspected from sensor to actuator. Process control functions are usually tested by first verifying the lower-level functions and then proceeding to successively higher levels.

A hierarchically organized process simulation would be desirable for functional testing, since only such a tool makes it possible to draw unambiguous conclusions as to whether the plant as a whole will also operate in the intended way. If such a simulation cannot be performed, as is still the case for most processes, this information cannot be acquired until commissioning (see Chaps. 3 and 11).

Commissioning is the initial operation of the entire plant, including process measurement and control equipment, by the operator. It is the last test showing that the process runs in the intended manner. Commissioning can thus be regarded as further quality assurance practice.

Commissioning is performed in three steps:

- Preparation
- Operation with "inert" media ("water run")
- Operation with chemicals

The first two steps are carried out by the departments involved in the planning, design, and erection of the plant. If the project has been contracted out, these steps are done by the outside firms together with the plant operators. The functions to be performed during commissioning are [653]:

Preparation
- Technical training of operating personnel (operating instructions)
- Technical training of maintenance personnel
- Safety training
- Stocking of spare parts and standby equipment
- Securing of feeds, auxiliary media, energy supplies
- Preparation of the plant (purging, drainage, venting, drying)
- Loading of the process measurement and control system

⋮

Operation with "inert" media ("water run")
- Commissioning of auxiliary systems (steam, cooling water, etc.); loops (heating water loops, etc.)
- Testing of safety features
- Simulated operation
- Testing in operating modes (startup, shutdown, load changing, etc.)
- Performance of needed amendments

⋮

Operation with chemicals
- Production test run
- Modification of process measurement and control equipment

– Guarantee run

⋮

After preparations are complete, the plant is started up with inert (i.e., unreactive) products, beginning with the auxiliary and service facilities. Next, circuits such as heating loops are commissioned. After the entire plant has been placed in operation, the safety devices are inspected.

The opportunity presents itself for a comprehensive test of all modes that will be encountered in later operation (startup, shutdown, load change). On the basis of the experience gathered, any amendments needed are now carried out. The documents are revised at the same time.

The next step is operation with chemicals, that is, a production test run. Responsibility for the plant ultimately passes over to the operator.

Ordinarily, a plant is started up at a low throughput and gradually brought up to rated output. The final modification of the process measurement and control equipment to the plant is carried out during this phase. Included in this modification are the adjustment of controller parameters, the input of limiting values, and so forth.

In particular, if the plant has been designed and built by an outside firm, evidence must be presented that the plant complies with the design as to capacity, yield, availability, and quality. This evidence takes the form of an extended test run. The plant documentation (see above) must be finalized at this time.

When commissioning has established quality, that is, shown that the process runs in the contemplated way, the project is over. A detailed final report is mandatory.

Figure 348. Relationship of plant and main wing

10.7. Process Control Rooms

Introduction. This section describes the requirements that process control rooms must meet, offers suggestions for their appropriate design, and reports operating experience [668].

In the context of optimal human – process communication, it is indicated what requirements, stemming from technical, ergonomic, and other knowledge, govern the architecture, construction, and outfitting of control rooms. The design suggestions are based on scientific publications, standards, guidelines, and operating experience. Details of execution can be found in vendors literature [669].

Architecture. *Relationship of Process Control Rooms to the Plant.* It is advantageous to locate process control rooms relative to the production facilities of the plant so as to create short paths for installation and for access to the plant. The control room should be on a level with those parts of the plant most often accessed. Control room location and structure must afford adequate protection [670].

The "main wing" layout (Fig. 348) offers an optimal way of meeting these requirements. Furthermore, direct connection between laboratory, superintendent's office, and social spaces promotes necessary communication. Protective functions are also taken care of, for example in relation to hygiene or safeguards against undesirable external influences.

In large-area combinations of facilities (Fig. 349), it may be useful to erect a freestanding control building to take over a variety of operational functions.

Figure 349. Layout of plant and control room buildings

Figure 350. Breakdown of the main wing

Arrangement of Control Rooms. Process control rooms and other rooms that house, for example, plant management should be laid out in a functional way so as to permit an optimal flow of operations. This can be done whether these spaces are located in a main wing (Fig. 350) or in a separate building.

The control room is the central area for the performance of essential process control engineering functions. Such tasks are described in the "level" model of information (see Section 2.3). The switch room for information processing holds the equipment necessary for processing and interpreting information. The switch room for electrical power distribution is the site of central process electrical equipment.

The control room and switch room for information processing should be located close together. The electrical switch room should also be placed in the main wing. If distances are long, however, electrical distribution for the plant can be housed in more than one switch room (to minimize cabling costs).

The central communications equipment for a plant needs its own room. Rooms for process analytical instruments should be placed at crucial sampling points in the plant. Special requirements apply to these rooms [671].

The following points, in particular, must be considered when positioning control rooms relative to the plant and one another:

- Safe access and escape routes
- Optimal cable and utilities routing
- Fire safety
- Favorable location for fire fighting if necessary

Space Requirement for Process Control Rooms. Space requirements can be determined with graphs or ratios derived from operating experience, which offer guidelines (Fig. 351, see next page) for initial control room design. The increase in individual functions expected through the end of the project has to be estimated and reserve space must be provided.

Starting with some minimum size (ca. $25\,m^2$), the space required for a control room is worked out from the number of process control stations to be observed and controlled. The figure of $0.1\,m^2$ per process control station is a lower limit for conventional instrumentation. The use of process control systems and process control computers will reduce the area needed.

The space required for the information processing switch room is also governed by the number of process control stations. A minimum figure is again $25\,m^2$. With conventional instrumentation, the minimum additional area required is $0.2\,m^2$ per process control station. The use of process control systems will cut the space requirement.

The installed power is the essential factor determining the needed area for the power distribution switch room; the minimum size is $15\,m^2$. About one square meter is required for every $10-20\,kW$ of installed capacity. If there are many variable-speed drives, however, the required area per kilowatt may increase.

Ergonomics. Ergonomics is concerned with the interrelations of human beings and the world in which they work [666]. Due attention to ergonomic factors in the design and construction of control rooms is a precondition for good

human – process communication (see also Section 11.2).

Figure 351. Space requirements for process control rooms

Anthropometry. Anthropometric considerations lead to guidelines for spacings, openings, and clearances in the placement of individual devices and equipment in control rooms.

Pushbutton controls, switches, and display elements should be arranged so as to allow optimal access and visibility (Fig. 352) [672, 673]. An important factor in determining the appearance and size of labels is the distance from which they will be viewed. When locating display and control panels, care should be taken that they are in easy view of the operator.

Figure 352. Optimal manipulation and viewing areas

Lighting. A variety of visual tasks must be performed in control rooms (Fig. 353). The type and intensity of illumination must be adapted to each such task [675]. Illuminances between 200 and 500 lux are recommended for error-free reading of meters and other readouts, illuminated symbols on panels, and characters on screens and displays. Lighting properly adapted to each visual task features separate, continuously variable brightness adjustments for the two zones. Fill-in lighting serves to enhance the local illuminance on printers, desks, and so forth. An appropriate configuration of lighting fixtures in combination with glare screens should help to prevent reflection from displays. Since control rooms are generally occupied day and night, the lamps should provide daylight-balanced lights in order to insure consistency in color and illumination.

Switchgear rooms should have an illuminance of 300 lux.

Backup lighting must be provided in control rooms and is recommended in switchgear rooms. Safety lighting must be provided for pur-

poses of accident prevention. Details of lighting design can be found in company literature [667].

Figure 353. Control room lighting

Climate Control. Ambient conditions in the control room must be held constant within a fairly narrow range [674]. Furthermore, because personnel are present at all times, there must be a continuous, draft-free supply of fresh air (5 to 10 air changes per hour; Fig. 354).

Figure 354. Ambient conditions

Switchgear rooms are not continuously occupied, and the tolerance range for the ambient conditions is therefore wider. In contrast to the control room, much heat is evolved here and must be removed by a waste-heat removal system. Computer components belonging to process monitoring and control systems may have stringent climatic requirements, which can best be satisfied by separate climate control devices.

Undesirable pollutants must be kept out of all rooms used for process control functions. A slight overpressure is therefore maintained in such areas; filtered fresh air from pollutant-free areas is delivered through special floor registers and extracted through ceiling grilles. The control room must have the capability of shutting down the ventilation of all rooms at any time.

Acoustics. Acoustic conditions in the control room should be such that personnel there experience no difficulty in understanding one another or in communicating with the outside world by telephone or intercom, and also such that acoustic signals can easily be detected by the human ear. Care should be taken that the noise level does not exceed the 55 dB (A) ambient noise, the reverberation time in the middle frequency range (500 to 3000 Hz) is ≤ 1 s, and the level of acoustical danger signals in an octave range lies a minimum of 10 dB (A) and a maximum of 20 dB (A) above the interference.

Control Room Design. *Doors and Windows.* On grounds of safety and health, pathways between the production facility and rooms that house process control functions may be equipped with airlocks. Airlock doors must be fireproof, self-closing, and gasketed, and they must open in the escape direction. Larger monitoring and control rooms must have a second emergency exit.

Because communication with the process takes place exclusively via process monitoring and control devices, windows opening into the plant are not needed for communication. Windows may, however, be required by workplace regulations [676]. When control rooms are located near explosion hazard areas, appropriately rated exterior windows must be provided.

Floors. Control rooms should be constructed with floating floors. Cables are led through floor penetrations or cable ducts placed in the floor (Fig. 355). A variety of special plastic floor tiles are available. Ceramic tile is used where contamination is severe. Double flooring in computer and switchgear rooms (Fig. 356; both figures see next page) permits free cable routing.

Ceilings and Walls. False ceilings are particularly suitable for control rooms. They offer a range of options both for concealing the unfinished ceiling and for the placement of functional elements such as fire alarm and fire-suppression systems, air conditioning, cable ducting, and lighting fixtures. Esthetic, acoustical, and cli-

Figure 355. Cable duct installation

Figure 356. Double floor

matic considerations require attention to not only the ceiling but also the walls. All other rooms that house process monitoring and control functions have ceilings and walls painted in light colors.

The control room should have an unfinished height of 4 m (to bottom face of ceiling joists). The height of the false ceiling should be 3 to 3.50 m, depending on the size of the room. A height of 3 m (to bottom face of air ducts) is recommended for switchgear rooms.

Ceilings and walls must comply with pertinent fire-protection codes (F 30 or F 90); this applies particularly to cable penetrations.

Desks (Fig. 357) hold visual displays and controls such as keyboards, light pens, joysticks, mice, and touch-screen input devices. Horizontally and vertically pivoting display bases permit adjustment to suit individual preferences [673]. Additional free space is needed, for example, to accommodate a radio and telephones and to permit occasional writing.

Operator stations in control rooms are used for monitoring and controlling the process. They enable the operator to intervene in the process as required. An operator station (Fig. 358) generally consists of a color graphics monitor or monitors and controls. The controls usually consist of a keyboard (with movable or touch-sensitive keys) for the input of commands and/or a light pen with which the process can be controlled directly on the screen.

Figure 357. Operator desk

Figure 358. Operator station

The light pen has the advantage that input errors are largely eliminated and performance speed is roughly doubled. Fatigue-free operation with the light pen is, however, possible only with the elbow supported, so that the monitor should be located only ca. 40 cm away from the operator. Other control arrangements employ tracking devices such as joystick and mouse or permit operation by touching the front of the screen (touch-screen devices).

Hard-copy devices and printers are used to document the process in printed form. They should be installed in noiseproof, dustproof enclosures in a readily accessible location (unless they have to be placed in a separate room).

The *process communications wall* comprises panels holding extra monitors as well as individual displays and controls (Fig. 359). The preferred configurations are straight, L-shaped, and U-shaped. Mimic flowsheets can be laid out along the top. The various functional elements are modular devices. To make the spatial organization clear to the observer, they can be arranged in accord with the production flow.

Figure 359. Process communications wall, furniture, and accessories

Furniture and Accessories. Besides the monitoring and control devices, the control room should be equipped with the following (Fig. 359):

- Bookcases for documentation as well as storage of supplies such as printer paper
- Desk/worktable
- Bulletin board
- Flip chart
- Wall clock showing date, day of the week, and time
- Storage for protective clothing and safety devices (e.g., respiratory protection, fire extinguishers). This should be placed where the operating personnel can access it quickly and without hindrance on the way to the plant.

11. Operation

11.1. Principles

This chapter discusses some points relating to process control engineering that must be borne in mind when operating process plants.

Along with reliability (environmental, occupational safety, and health issues) [677–679], the most important quality of process operation is reproducibility. In other words, the required product properties [680] of the end products must lie within the respective tolerances (see also Fig. 34). The same applies to all relevant intermediate species, of course. Product properties should always be regarded as "primary nominal values" [681].

As shown in detail in Chapter 2, product properties are described in terms of individual process elements. These in turn are described in terms of process properties [680]. Process and product properties are linked by transformations expressed in "operators," and the product properties can thus be represented as functions of the process properties [682, 683]. Gilles [684] takes this a step further and, in a first formulation, allows the set of product properties in the production process to be categorized as a state variable.

Because the above properties or attributes are mostly multidimensional aggregations, it is meaningful to refer to "product spaces" and "process spaces."

Thus, to achieve product properties complying with the requirement profile, the respective process properties must be maintained in each process element. These in turn have their own requirement profiles with corresponding tolerances. These requirement profiles of the process properties in each process elements are to be understood as "secondary" nominal values or setpoints. They are constituents of the control

Figure 360. Nominal/actual comparison for a production process

loops (generally involving thermodynamic and reaction-kinetic quantities) in the process control system.

Figure 360 shows a nominal/actual comparison for a production process. This representation is the most important piece of information required for controlling the process. Detailed discussions can be found in Sections 2.3 and 11.2.

When production processes are to be optimized with respect to certain target quantities, process models must be created. These are math-ematical descriptions including the interdependences of process properties as well as the dependences of product properties on process properties. As shown in Chapter 3, models can be subdivided into purely empirical or statistical models and "theoretical" models.

Statistical models are derived from the actual (measured) product and process properties in the real process running in a pilot or full-scale facility (see Fig. 360 and Section 3.2). Its equations are purely mathematical in nature. It is difficult to assign physical interpretations to its variables by using techniques to reduce the dimensionality [685, 686].

Static and dynamic process models are essential for effective simulations.

In general, "simulation" refers to the use of information technology to forecast the behavior of the independent variables in a system when the independent variables or the initial and boundary conditions change [687, 688].

Provided the basic model (see Chap. 3) can be formulated in explicit mathematical form, the fundamental problem is to find suitable numerical procedures for the economical solution of the mathematical problem. As interactive communication between humans and the process becomes more important, the graphical presentation of the data model or functional model (see Chap. 2 and [689]) is gaining in significance [682].

Problem-oriented "object spaces," with the "attributes" of the objects as their coordinates, should be designed so as to promote human thought and learning (see Section 11.2). Information reduction is a key tool to doing this.

This holds both for training a user concerned with a technical, economic, or sociocultural system (see Chap. 2) and for devising solution aids for finding "optimal" operating points. Zeitz [687] is therefore justified in according the highest importance to such simulation. The framework for system modeling must be extended beyond the customary metric scaling into the realm of topology. In con-

trast to well-known solution approaches, simulation thus takes in predominantly algebraic and differential-equation-oriented structures as unified topologies of knowledge, as suggested by GILLES [690], in his discussion of knowledge-based process control engineering. Numerical and knowledge-based solution tools will have to be harmonized with one another in the future. For example, the NAMUR Status Reports include noteworthy articles offering many suggestions and solution approaches [691–697].

The modern model-aided procedure will also lead to new and expanded safety concepts. These include concrete approaches to the early detection of hazardous conditions based on model-aided measurement methods [680]. Experience in biotechnology also suggests that applications will appear in prognostic medical diagnostics.

One of the principal tasks of process control engineering is to increase the degree of computability in each process step and to represent it in suitable process models. However, only a purposeful collaboration with process engineering can lead to a fruitful symbiosis here. This holistic mode of analysis will be established in a new engineering discipline, process technology [698]; see also Section 11.3.

Representations that are closely related to the phase model of production are the Petri nets [699]. While the phase model represents the topology of product flow, Petri nets describe the system of conditions governing product flow. In the context of Petri net theory, any technical system can be represented in terms of two description categories:

- Existence of a state
- Occurrence of an event

Each state is terminated by at least one event and/or brought into being by at least one event [700]. States can also be interpreted as conditions that must be fulfilled for a transformation specification to be carried out. In order to describe the dynamic sequence, a further description element – the token – is introduced. The token moves through the static net as a traffic unit. The total population of the net by tokens characterizes a global state of the net.

The central modeling aspect of Petri nets is the concept of concurrency. Two events are said to be concurrent if they are causally independent of one another [701].

In processes, buffers are used in an attempt to decouple the flow of material and prevent disturbances propagating through the entire plant. Subsystems decoupled via buffers can operate independently of one another, that is, concurrently, within certain limits. In this way, Petri nets can be applied to production processes. The net theory offers the possibility of modeling such systems and determining their dynamic properties by computation or simulation. Local analysis and modeling has two effects: It reduces the complexity and it creates the possibility of using a process-logistical procedure along with decoupling via buffers [702].

In automatic mode (for which recipe-mode operation is a prerequisite), the process-logistical problem (Table 14) [703, 704] is that multiple intercoupled process elements operating in distinct modes must be managed in terms of their mass flow. The definition of operating modes is less well-known than the "recipe" concept discussed above. It describes all modes of operation within a process element, including exceptional and disturbance situations, in discrete form. It must be set in phase-specific fashion for the batch case and section-specific fashion for the continuous case. For a continuous process element and its transitions, the various operating modes are shown in Figure 361 [705]. Because of the wide range of possible mode specifications for various process elements, the process states desired in disturbance-free operation and the process states sought when disturbances are present are specified as functions of the instantaneous state, in well-defined steps, or are calculated in real time and set down in control tables. The contents of these mode-specific tables are derived from simulation calculations or experimental data.

Figure 362 shows schematically how the categories of importance for operation – reproduction, optimization, and automation – are interrelated.

WÜCHNER [706] has discussed which requirements apply to personnel when modern process control systems are used. KRAUSS [707] sees the acceptance of process control systems operating in information-oriented fashion as essentially insured by correct design of the display and control components of the control systems.

What applies to communication between humans and the process control system is equally

Figure 361. Operating modes of a continuous process section and their possible transitions [705]

Figure 362. Reproduction, optimization, and automation

Table 14. Levels of automation

Process elements	Mode	Necessary information management	System hardware	Characteristics	Realization
Decoupled	1 manual	all flow paths and all process/product properties manually input as setpoints, managed, and documented	all sensors, all actuators, individual controls and control systems	reproducible production in all operating modes (process models)	$\geq$75 %
	2 computer	all flow paths and all process/product properties input to computer as setpoints, managed, and structured in documented form BF∗: switch net; set parameters; BF∗ provided with setpoints	as in 1, plus PCS∗ with BFE∗ and BF∗, PCC∗	reproducible production in all operating modes with recipe operation, process models, simulation, optimization	$\leq$20 %
Coupled	3 logistical	as in 2, plus buffer management, buffer strategy, source-point management	as in 2	buffer strategy-oriented recipe mode for all operating modes	$\leq$1 %
	4 automatic	as in 2 and 3, plus control of divergence of process elements through variation of process properties	as in 2, plus net orientation (Petri nets)	divergence-oriented recipe mode for all operating modes	1995

∗ BF = basic function; BFE = basic functional element; PCC = process control computer; PCS = process control system.

important with regard to the sensor systems, which serve as "eyes" on the process [708].

After this general discussion of operation, the following sections deal with human – process communications (Section 11.2), process analysis and process optimization (Section 11.3), and maintenance strategies (Section 11.4).

Human – process communication comprises the integration of information acquisition (sensor technology), information processing (control system), information and knowledge utilization (human component), and information feedback to the process (actuator systems). The totality of these processes (Fig. 363) insures proper operation of the process.

Process analysis and process optimization aimed at achieving permanent gains in reproducibility, safety, and economics is a single engineering task from the viewpoint of process control engineering.

Maintenance strategies aim to preserve and improve the availability of the production facility and its process control components.

Figure 363. Human – process communication

11.2. Human – Process Communications

Introduction. Humans today are surrounded by a great number of technical processes. In production, new products are made from many elements by combining operations. Production arrives at new products through the reaction of feed materials. Energy generation and distribution processes are of major importance. Other important technical processes permit the transportation of people, goods, and information on land, by water, and in the air.

The human role in all these processes is to monitor and control. This can be carried out in a "planning and forethought" mode. The human optimizes technical processes as to structure and sequence, detects hazardous situations in the processes at an early stage, and can then intervene promptly to remedy them.

The complete interaction between human and process, which is gathered together under the phrase "human – process communication" in what follows, is governed by the operator, working at an operator station, who runs apparatus and devices, observes measurements, and alternately abstracts and concretizes in an attempt to comprehend what is happening in the process on the basis of individual-signal observations.

In a production process, information relating to an individual process apparatus is accessible at the individual measurement stations still to be seen everywhere (Fig. 364). There are also very large control rooms (Fig. 365) in which information from large plants is gathered together and displayed on consoles and panels. The color graphics display (Fig. 366) is a modern alternative offering an easily and quickly comprehensible representation, even for complicated processes.

Any production process has an a priori dependence on the combined functioning of physical, chemical, and other sensors, which provide the human operator with knowledge about the properties of products and processes by means of appropriate information processing. Automation of production processes, in contrast, leaves process events in a state that can ultimately be comprehended by human senses, except as required by systems-engineering and social-psychological exigencies [709].

The preceding chapters have taken up the problem of what information should be determined for process control purposes (see Chaps. 2, 3, and 7 and Section 4.5). Now to these is added the question of which presentation of the available information is best suited to human communication abilities. Modern resources of information technology hold much promise in this area. As yet, however, there has been no ex-

Figure 365. Large control room for monitoring operations

Figure 364. Individual measuring stand in process engineering

Figure 366. Color display with light pen and keyboard (Siemens Teleperm M [762])

act study of their capabilities in the context of information-oriented process control.

Shortcomings are often seen in the selection and presentation of information as commonly performed at present. For example, an intermittently severe cognitive stress is imposed on operators in "exceptional" situations, which include not only changes in operating values in continuous plants (startup, shutdown, load change), but also unforeseeable changes at the dispositive and operative levels. Ironically, plant automation often leads to a high degree of monotony during normal operation [710], which can be blamed on the supply of information being inadequate for the performance of additional duties within the sphere of competence [711].

Besides the proper distribution of tasks between human and information-processing systems (see Section 7.1, Fig. 241), the responsibility for the control of a process is a question of some importance. The question of what information is "appropriate" becomes significant, although it must not be forgotten that furnishing such information is a necessary but far from a sufficient condition for any assumption of responsibility [712].

This section discusses the general problem of human – process communications for the example of a production process. In discussing the procedures and systems used, reference is also be made to other technical processes.

The special problems of machine-level monitoring and control, grouped under the heading of MMI (Man – Machine Interface), is not the point of focus here, although at times it will be necessary to point out crucial differences between MMI and MPC (Man – Process Communication). A helpful introduction to human – machine communications can be found in [713]; a useful reference work is [714].

First, it will be beneficial to survey briefly the capabilities of humans in their interaction with large bodies of information today. In the commercial and administrative sphere, the high-speed printer serving as output medium in computing centers generates long columns of numbers and symbols on tall stacks of paper (Fig. 367); this device continues to play a central role. The term "business graphics" refers to a mode of presentation that is more suitable for summarizing complex information (Fig. 368).

Until recently, engineering devices first took form on the drawing board. Computer-aided design (CAD) marks the beginning of a new world in which design is supported by all the resources of modern computer technology.

Figure 367. High-speed printer with tables

Figure 368. Business graphics

Acquisition and Presentation of Information. In earlier centralized process control and more recent decentralized systems, all relevant information about the technical process (and today also about the distributed process control system) must be assembled at a central location so that process control can be optimized under holistic criteria. This central process control location must also have a high availability so that operating personnel can carry out monitoring and intervention at any time. High availability is also required because process condition documentation is often mandated by law.

Human – process communication began in the early 1900s with direct display and control by field-level devices (Fig. 369). The re-

Figure 369. Development of process control room design [710]

sults gained, together with the development of auxiliary-energy field devices, led to a concentration of such devices in a local control stand. Increased plant size and more stringent documentation requirements, aided by unit controllers and modular control systems, led to the central control stand with a flowsheet-like representation of the process around 1950. This flowsheet technique has several advantages for human – process communications:

- The process structure (or "process topology") and the condition of the process are displayed together. An example is the combination track diagram and signal/control box used by the German Federal Railway (Fig. 370).
- The assignment of control and display elements to the process is implemented through a suitable configuration in an abstract, graphically represented process structure. As a result, control elements can be directly addressed and actuated while their place in the process structure is clearly shown.

With increasing process size and number of process states, the space requirements and costs of hardware process flowsheets have grown. In the case of extensive processes such as those in the petrochemical industry, process control rooms employing flowsheet displays are up to 100 m long and can be managed only by a correspondingly large and mobile staff (Fig. 365), hence the names "bicycle" and "rollerskate" contol rooms. High costs of creating such a display are followed by high costs of modifying it, so it is difficult to alter the flowsheet-type control room to keep up with changes in the technical process.

Figure 370. Combination track diagram and signal/control box used by the German Federal Railway

From 1965 on, increasing plant size and the growing number of display and control devices in the central process control room – along with the availability of central process control computers – led to the central control stand with block structure (Fig. 371), similar to the quick-scan display technique used in aircraft design. Control rooms employing the block-structure principle have the following features:

- Like instruments are placed in groups
- The relationship between operating and display elements and the technical process is identified by names (nameplates)
- The control and display elements are selected and actuated indirectly; there is no direct topological relationship to a graphical representation of the process.

Figure 371. Central control stand with block structure

The operating personnel must therefore remember the process structure. It takes several steps to select and actuate the control and display elements, and this operation calls for good memory and abstraction abilities. The purely technical capabilities of the block-structure control room as to modification are certainly superior to – and more user-friendly than – those of the flowsheet-type room, but it is more difficult for the operating personnel to keep up with frequent changes in the room.

With the availability of powerful and economical computer-supported color displays, the representation methods of the block-structure control room can be retained and adapted to the capabilities of the display screen.

The most important types of video display now in use are discussed on the basis of the control and monitoring devices employed in the process control systems TELEPERM M [715], MASTER [716], and Geamatics [717].

Figure 372 shows the general block-structure principle with color graphics displays, with details presented in Figures 373, 374, 375. These are standard or predefined displays and exist as prefabricated data records with the basic representation of images for plant areas, groups, and individual control loops. All the designer must do is adding plant-specific data to this data record (see Chap. 8).

Figure 372. Block-structure principle with color displays [703]

Figure 373. Summary diagram [715]

The so-called free display is the exact opposite of the standard displays. Here the designer has a totally free hand. Standard symbol sets offer an aid; elementary symbols can be com-

Figure 374. Group diagram [717]

Figure 375. Loop diagram [716]

Figure 376. Free display [715]

bined to make new symbols or a toolbox with elementary graphics objects such as circle and rectangle. The designer can thus represent anything from a valve to a steam boiler. If certain symbols are not included, a new symbol set can be put up on the screen. Separately stored subimages can be inserted into various overall images, thus saving much time. State displays are also easy to create. In on-line operation, they appear on the screen with the true values, thus facilitating a nominal/actual comparison. Many such free displays can be stored in the operating computer as a data record and can be scrolled through sequentially (Figs. 376 and 377).

Standardized menus simplify the creation of curves and groups of curves, the assignment of curves to measurement stations, the assembly of curves into full plots, and the specification of storage form, display form, measurement range, and unit of measurement. The system may request all these details in interactive mode.

Curve plots can be presented in a standard or free display. Depending on the physical input device, the selection is made by pointing to a digital or a bar-graph display with a light pen (Fig. 378), touching a touch screen, or using a mouse or trackball to position a cursor. Curves are shown in windows with the required deeper level of detail.

Complete standard images can also be incorporated in these windows, for example, the standard representation of a plant group. Win-

Figure 377. Free display [717]

Figure 378. Curve plot [715]

dow support makes process displays far easier to understand, since only the permanently needed information is always visible; details appear in the window only when needed. The window size and position are determined by the designer; in modern systems, they can be modified on-line by the user (Figs. 379 and 380).

What is more, user procedures and reports can be freely designed. In doing this, the user determines everything: size and layout as well as dynamic information up to the way in which report creation is initiated. Reports can be generated by specifying a start time and a printing cycle (shift report) or certain events (charge re-

Figure 379. Windowing: standard displays in free display [712]

Figure 380. Windowing: standard displays and control panel in free display [716]

port). All reports can be retrieved at any time, for example, in order to reconstruct a certain plant state (Fig. 381).

Thus the windows technique pioneered by Xerox PARC, Apple Macintosh, and Microsoft has found use in color display components of process control systems.

The supplementing or replacement of the block-structure control room by the introduction of color video displays has also changed the mode of operation. In keeping with the concept of furnishing information about the process and product properties, apparatus, devices, and field-level (local) and process control systems to a central location at all times as needed for process control, additional analysis of the identification and selection of the desired information was required. The search for input techniques

that place an a priori limitation on the number of possible errors has led, for example, to the selection of well-defined screen regions by touching with a light pen, thus avoiding erroneous digital input. The touch screen is another approach to the same problem. Efforts to optimize "input technology" are related to the topics of accuracy, speed, and physiological and psychological burden on the operator. These points are discussed in [718, 719].

Figure 381. User report [711]

At this point, a fundamental difference between human – machine (man – machine) communication (MMC) and human – process (man – process) communication (MPC) should be emphasized. While MMC is based on a specified content and context of the information and goes on to formulate conditions such that the information flow through the human – machine interface will be suited to human capabilities, MPC is concerned with tasks arising in the course of process control and the information that must be furnished so that these tasks can be performed. From, this standpoint, the first questions raised in MPC relate to historically accreted information structures, which are largely oriented toward apparatus, devices, and control loops, and which supports the interpretation of information in precisely this context.

After a thorough analysis of the contributions made by the operator to process control (see Section 7.1, Fig. 241, and Section 11.1, Table 14) and the information that must be made available for this purpose, the design of human – process communication must take account of the "cognitive faculties" of humans, which also serve as the basis for the delivery of task-relevant information. Findings from psychology have a role to play here.

Interface design in software engineering and cognitive engineering employs an approach borrowed from cognitive psychology in which human beings and their communications capabilities are examined in terms of the "information processor" paradigm. An introduction to the principles and limitations of this approach can be found in [720].

According to the conceptual models of cognitive engineering, humans act on three planes (Fig. 382) [721]. First, from sensory afferents and associated arrays of features, signals are derived through training and directly transformed into actions (intuitive behavior). The second level of behavior is based on rules selected in accordance with a recognition procedure and the association of state and task. Finally, knowledge and experience are turned into goal-dependent decisions, which lead via a planning process to new rules of behavior. Clearly, the last two cognitive levels require a greater information-processing effort.

Any arrangement for human – process communication must therefore use an ingenious array of features and representation of the process state to provide especially good support to, for example, the "intuitive" level if the human operator is required to react quickly in the course of a monitoring task (such as to issue an alarm). In tasks having to do with quality, where links between process and product properties must be discovered and analyzed, possibly over wide spans of process sections, the cognitive faculties of the two higher levels should be supported in the model. According to ideas of cognitive engineering [722–724], this can be accomplished by providing information at various levels of detail or by using a rule-based advisory system (expert system).

How individual mental activities involved in operating and monitoring a (partially) automated technical process can be supported by appropriate software has been shown in [711]; see Figure 383.

In a paper titled "Mozart, or Our Dilemma When Dealing with Genius," Eigen [725] quotes from Eccles' work "The Human Brain" [726]. Here, a similar distinction is made between the dominant hemisphere, which controls conscious behavior in an analytical, logi-

Figure 382. Levels of human behavior [721]

cal, comprehending way, and the subdominant hemisphere, which reacts in a musical, graphical, holistic way: This can be understood as implicitly relating to various human information-processing cababilities. Thus, pictorial representations, including graphics, make information comprehensible in a chiefly synthetic (holistic) manner, while texts appear to stimulate analytical, sequential thought.

Deepening the understanding of the perceptive, cognitive, and memory procedures of the human brain is the realm of psychologists. A guide to the abundant literature of psychology is given in [727].

Psychophysics deals with the quantification and scaling (see Section 2.3) of psychological meaningful phenomena. It studies the relationships between the "objective" features of the thing perceived, the underlying physiological processes, and the experience of perception. Gestalt psychology has also made contributions in this area [728]. Findings from these sciences find use today in software ergonomics among other fields [729]. Recommended intro-ductions to physiology are [730, 731]; an exposition of perceptual psychology is given in [732].

Now that magnetic-resonance and positron-emission imaging techniques have made it possible to localize functions of the human brain by functional activation of localizable glucose metabolism [733–736], neuropsychology may provide a bridge between physiology and psychology. Results from this discipline that may be significant for human – process communication are eagerly anticipated in [737].

A fundamental dispute between purely scientific-positivist and phenomenological-anthropological modes of analyzing psychological processes, in particular the concerns of perceptual psychology, was shown by Straus as early as 1936 [738]. Straus warns urgently against allowing an anthropomorphic interpretation of mechanical activities to be turned into mechanomorphic interpretations of human and animal behavior. Similar statements have been made by other members of the "holistic" school, such as Eccles, Popper, Lorenz, and Gibson [739]. They point to fundamental problems in the reductionist approach when regarded from the standpoints of neurology, philosophy, biology, and perceptual psychology (see, e.g., [726, pp. 34 ff]) and show how specific human abilities might be understood in terms of the integration of subfunctions and how the preconditions could thus be created for participation in

Figure 383. Support of operator's mental activities by interactive and custom software in the control and monitoring of an automated technological process [711]

supra-individual "worlds" such as culture and science (see [740, pp. 148 ff]).

The presentation of messages relating to the technical process must be oriented toward specific target groups of users. This does not simply refer to the experience, for example, that the message coding must correspond to the importance of the message itself – which is reflected in varying reaction times (Fig. 384) – or to the limited field of view of human vision (Fig. 385); such experiences must be taken into consideration when designing process control rooms and in particular when setting up the configuration of monitors [741] (see also Section 10.7).

The presentation of information must also take into account that process engineers, for example, need a different view of the process from day-shift or night-shift operating personnel, whose spectrum of tasks extends from process analysis and optimization to straight operation of the process in accordance with stated rules (Figs. 16 and 386).

Figure 384. Reaction times to messages encoded in various ways [735]

Figure 385. Field of human vision

Figure 386. Process communication

Modern process control systems, with their display and control components, furnish a flexible tool with which, using the many individual process signals available, process states can be represented in an anthropotechnically and economically favorable fashion. As Figures 372–381 show, operating personnel build their own models of the technical process, based on the individual signals, so that they are then able to interpret these signals correctly and take appropriate action to control the process state.

The availability of high-performance computers suggests using the computer itself to compress individual signals into an overall view of the process – an image or, mathematically speaking, a model of the process – and conveying to the operating personnel this compressed information based on the individual signals. This would complete the transition to "information-oriented" process control engineering. In signal-oriented process control, the information philosophy was: "Acquire and present information item by item, in parallel, and always."

In information-oriented process control engineering, the philosophy can be reformulated as: "Acquire information in the smallest possible amount, but as much as necessary, and not until it is to be used, and in a form that is clearest for the operating personnel".

Thus a holistic point of view will make it possible to enhance the competence of the operating personnel with the objective of "state-oriented" human – process communication.

Information Reduction (see also Section 3.2). Complicated technical processes generate a large number of signals, which the human operator cannot take in and interpret in direct form. For example, if two dozen signals are plotted in bar-graph form, the task of deducing certain process states from certain patterns can generally not be performed by a human. Procedures of signal processing and pattern recognition must therefore be employed to reduce this complexity.

Several methods for reducing the dimensionality are known, for example, from speech processing [742]. Orthogonal transformations, the best-known of which is the Fourier transformation, play an important role in this procedure. The idea is to represent an original signal by a linear combination of sine and cosine signals differing in frequency and phase. The weighting factors in the linear combination are the new dimensions, the number of which can be reduced by leaving out, say, high or low frequencies, with no substantial effect on the signal form.

Another orthogonal transformation is the Karhunen-Loève transformation, in which sines and cosines are replaced by functions derived from the original signal. These are represented as vectors whose contributions to the total signal decrease with increasing ordinal number. By forming a linear combination of a few such vectors, the original signal can be reconstructed well; the weighting factors in the linear combination are the new transformed signals with smaller dimensionality [743, 744].

The method of factor analysis takes the large amount of possible information about the product and the process and generates a system of mutually independent new variables that can be ordered, so that it is possible to say how much

each of these new parameters contributes to the total information.

If such methods are used uncritically, the problem arises that the new dimensions may not lend themselves to ready interpretation by the user. For example, signal mean values and signal ratios are highly suitable and are also subjectively accepted as indicators.

This discussion has mentioned and briefly described just a few methods for reducing the dimension. Applying such a method also reduces the redundancy, since as a rule a redundant signal can be represented as a combination of other signals, so that recovering them does not supply any new knowledge about the process state.

This situation typically occurs in an overinstrumented system where there are, for examaple, more sensors than are required for an unambiguous determination of the state. However, overinstrumentation also makes it possible to carry out signal reconstruction for signal sources that may have failed because of some technical defect (redundant instrumentation).

Even though there may be substantial time shifts between signals, especially in extended technical processes, there are deterministic relationships between them (e.g., measurements upstream and downstream of a lag element). In many cases, such shifts can be detected by cross-correlation analysis, but in general the result for a signal source is that not only the measurement at a time T but also some number N of measurements obtained at earlier times must be taken into consideration (see Fig. 387).

Figure 387. Schematic diagram of pattern recognition [735]

Pattern-recognition techniques afford still more support to the operator. For example, hazardous states in a process can be detected on the basis of a pattern in the signal. Figure 387 illustrates the principle of pattern-recognition systems. The original signals are first subjected to feature extraction. This is analogous to the dimension-reduction operation described above; the smallest possible number of features, and hence highly informative features, are derived from the original signals (see also Chap. 2).

This means that the subsequent classification can be done in a space of few dimensions. Classification involves forming regions in the N-dimensional feature space, under the assumption that patterns lying close together in feature space belong to the same class. In a two-dimensional feature space, such regions can be delimited by, for example, a chain of line segments.

If these lines are drawn automatically, possibly with operator interaction, the classifier is said to "learn." Under certain circumstances, depending on operator behavior, such a classifier may be able to adapt to changed process situations.

By using cluster analysis [745, 746], class formation can be carried out automatically without external supervision. Each new pattern is assigned to the region (cluster) to which it is closest. Cluster analysis can be used, for example, to find automatically and subsequently identify particularly frequent and typical process states. In future, this type of procedure will undoubtedly provide significant aid to the operator (see also Fig. 422).

These order-reduction procedures make it possible to represent process states in three-dimensional form, making it possible to visualize the product or process space (Fig. 388).

Figure 388. Analogy between product and process spaces [743, 744]

A similar mode of analysis is arrived at if the methods of similarity theory are applied to a signal pool [685, 686]. The direct presentation of the dimensioned X-quantities in X-space with X-relationships is replaced by the dimensionless presentation of π-quantities in π-space with π-relationships.

The presentation of state spaces, as a prerequisite for "state-oriented" human – process communication [711, 747, 748], requires procedures

by which relationships between the process and product properties can be obtained from the time dependences of these properties (as conventionally supplied by the instruments currently used for process monitoring).

Thus the problem is to derive the function $X_i(X_j)$ from the time dependences $X_i(t)$ and $X_j(t)$ of the measurements.

It is straightforward to plot the last N pairs of values (X_i, X_j) acquired to give a two-dimensional scatter diagram in coordinates X_j versus X_i. This representation may actually make it possible to derive the desired relationship. Under some circumstances, regression methods can also be used; for example, the mean and dispersion of X_i can be obtained for each X_j product. Utmost care is advisable, however, because no a priori prediction can be made as to the form of the curve.

Two further difficult time problems must be solved:

- In general, the function $X_i(X_j)$ is not stationary. Otherwise it could be determined once for all and would have no predictive power for the operator. The time constant that describes the behavior governs the size of the "window" over which the function $X_i(X_j)$ can be determined. The window may be fixed (a new measurement vanishes every time a new scan takes place) or decaying (e.g., exponential); the computing effort required is then less. The operator receives a picture of the function that shows a continuous slight variation.
- X_i and X_j may be very closely related but with a (possibly long) time shift or bias. If the X_i and X_j measured at the same time are plotted, the result may have no predictive power at all (Fig. 389).

The time shift can be identified by cross-correlation analysis, after which measured values $X_i(t)$ and $X_j(t+\Delta t)$ can be paired. It is also possible to create a three-dimensional representation with the time offset as the third dimension. The resulting "mountain range" would reveal where the dependence was most distinct. Changes in time offset, in any case, provide an important indicator of the process state (see also Section 3.2).

Figure 389. Effect of time delays

Information Storage under Real-Time Conditions. In future human – process communication systems, a major role will be played by the computer's internal data model [749–752]. This model must contain all data acquired and stored during the operation of the process control system (see Chaps. 2, 9, and particularly 8). Such a procedure will require data storage under real-time conditions, and this objective has given rise to the conception and development of real-time databases. The following typical features distinguish these from classical databases:

- They contain instantaneous data generated and required in real-time process operation. In addition, there are data to be archived for infrequent later interpretation. These archival data will replace the process logger charts common today; the large bodies of data acquired will typically be stored on video-disk memory devices. A real-time database, in the narrow sense, is concerned with the management of instantaneous data.
- These databases are very small in comparison with commercial databases.
- Reaction-time requirements are stringent, both for the storage of data (which must always be carried out such that a consistent data model is preserved) and for its retrieval (since such requests may be made by both the process and the operator). Reaction times in the millisecond range and very short time inter-

vals for insuring data consistency are needed here.

In the implementation of real-time databases, the result is extensive utilization of main memory.

The use of a real-time database in human–process communication systems will lead to major simplifications in programming. With the software tools belonging to a data base, individual queries can easily be handled; support of a query language with graphical output resources will simplify interaction with the operator.

Graphical Technology. EIGEN [685] has shown that pictorial representations (graphics) make it easier to comprehend information than does text.

The use of computer graphics in mathematics and the natural sciences is surveyed in [753]. Graphical kernel systems such as GKS/GKS-3D or PHIGS/PHIGS$^+$ are device-independent basic software systems for graphical programming; implemented on workstations, they increasingly form the basis for CAD tools [752,753]. Multidimensional state-space representation, in particular, requires images with almost photographic realism; today these can be generated with efficient algorithms and data structures or with ray-optics techniques from physics (ray tracing) [754].

Finally, computer graphics can handle demanding visualization tasks only with the aid of knowledge-based methods. Conversely, as discussed in Chapter 13, increasingly complex artificial-intelligence (AI) systems depend on graphical visualization aids to create viewable images of models and states. As a result, the disciplines of graphical data processing and artificial intelligence are becoming more and more interwoven, as is reported in [755].

What follows is a discussion of the graphics techniques available in current process monitoring and control systems. All graphical output devices now in use for human–process communication are color displays. Graphics systems in first-generation process monitoring and control systems feature medium resolution (roughly equivalent to the broadcast television standard) and permit the semigraphical representation of process states and process flowsheets. "Semigraphical" means that the screen is subdivided into predefined fields containing, for example, 8×8 pixels, in each of which alphanumeric characters or graphical image elements can be placed. A character generator driven in an 8-bit code contains the bit pattern for the characters and the selected graphical elements.

The refresh memories in modern systems are too large to be displayed on the screen. Thus the process image can be moved back and forth so that the screen appears to represent a segment of a large landscape (rolling image).

On the input side, the keyboard is complemented by a variety of pointing devices. These facilitate both graphical input and selection from menus shown on the screen. Typical devices for this purpose include trackballs; joysticks; touch screens, in which various physical methods are used to detect the location of the finger touching the screen; and light pens.

Each of these systems gives x/y coordinates on the screen, which are accepted as inputs to the operator software.

The trend in development of graphical devices for display and control components is toward pixel-oriented color displays. These offer much better resolution as well as physical parameters (19″ and 21″ screens with resolutions of 1280×1024 dots, displaying 256 colors simultaneously out of 16.7 million). There is a trend toward the standardization of hardware and software. The devices are based on PCs or workstations with RISC processors and run under operating systems such as DOS, UNIX, or their derivatives.

The principle embodied in these user interfaces is splitting into components that are relevant for the user interface and those that are specific to the processing tasks in an application [756]. The distinguishing feature from the user's standpoint is the structuring of the entire screen area in movable, variable-size, iconizable subregions or windows, which can accept user input and display representations independently of one another. Screen windowing and network-wide window management tasks are performed by basic windowing systems, which are included in the operating system or added on as utility libraries (e.g., Xd Windows [757]). "Network-wide" means that the user, from any network node, can interact with an application running on any other computer(s) in the network. One possible principle for such interaction is the client-server principle. Above the window manage-

ment level are graphical user interfaces (OSF-Motif, Open Look in the UNIX environment, MS Windows or Presentation Manager in the DOS environment).

The problems relating to control and monitoring components (see Chap. 7) have now impelled a number of manufacturers to create their own process visualization features for certain information-processing systems that have no display and control components of their own, especially systems based on stored-program controllers. One of the main components of these visualization devices, which can simultaneously carry out control functions, is a database system permanently linked to the process and hence running in real time. Because only a few of the user interfaces based on the well-known operating systems have been standardized (e.g., X-Motiv in the UNIX realm or Windows in the DOS environment), a number of very diverse "artistically" designed tools have appeared in this area. These require an extremely critical examination before they are put to use.

Several systems based on this architecture have been offered especially for process visualization (e.g., InTouch [758], Factory Link [759], APROL [760], Dynavis-X [761] COROS-LS-B [762]). Some process monitoring and control systems have integrated display and control components (e.g., SATTLINE [763], Viewstar 750 [764], Advant-Station [766]). The discussion that follows introduces special characteristics of these systems without describing individual products.

The functionality of these systems is outstanding because elementary, interactive, and scalable graphics objects are available. System resources, such as fonts, fill patterns, and color tables, can be utilized, and raster or bitmap graphics, either scanned in or generated by other graphics software, can be incorporated. With the aid of these design resources, predefined graphical input and output objects specific to process control engineering can be created and placed in libraries for later use. These include virtual keys, switch panels, slider controls, analog displays, and so forth. Another aspect of the graphical functionality is the "logical zoom" function, in which excerpts of images can be displayed in varying sizes and levels of detail and information is added as the zoom level increases [761].

Visualization systems based on graphical user interfaces are further characterized by expanded capabilities for defining the interaction (dialog) between user and process. These features include the interpretation of user inputs, the execution of appropriate commands, the creation of graphical objects when certain events take place, and so on. Along with well-known event-oriented and data-oriented concepts, complex control structures made up of command sequences, branches, and loops can be initiated, windows can be opened and closed, and graphical objects can be created and deleted. Flexible, state-dependent image structures can be built up in this way and need not be oriented to fixed image hierarchies.

Another characteristic is that these systems can be set up to utilize open system services present in any hardware and software platform so as to expand the process visualization functionality. Such mechanisms include system services for data exchange, command transmission, and simple integration of application-specific software upgrades. Examples are Dynamic Data Exchange, the Dynamic Link Library concept and multimedia add-ons under Windows and (in part) OS/2, database query languages such as SQL, and pipe mechanisms under UNIX. In this way, open visualization systems offer better integration capabilities than the display and control components in first-generation process control systems. One example is the connection of the visualization system to a spreadsheet analysis in which process data can be linked with mathematical functions on-line. Unified operator control concepts in a user interface come into play here because different programs then present themselves to the user with the same appearance mode of interaction (dialog). The utilization of system services also includes the possibility of creating help systems and defining macros.

For the designer of a process visualization utility, ease of use dictates that the capabilities of the graphical user interface be employed in design. "Toolkits" or interface modules are not adequate for this purpose. They merely provide development interfaces at the programming-language level and require much specialized knowledge. Abstraction levels suitable for the design of display and control components offer classes of tools, such as CAD-like editors for graphical interfaces in combination with editors

for formulating "interactive" control, so that interface objects can be selected, constructed, furnished with attributes, and linked to user actions and process data (interface builder and user interface management systems [756]). Resources taken over from the CAD world, such as traps in conjunction with underlaid rasters, further facilitate the work.

From the process control engineering standpoint, the high flexibility of visualization systems also holds some risks. In the design of process visualization, the assignment of appropriate parameters should be used to restrict the user's options in interactive mode. For example, it should not be possible to place other windows on top of alarm windows. Similarly, a basic subdivision of the screen into fixed-position, fixed-size summary and detail windows should be permitted. Application-specific software add-ons and process data manipulations in other software packages may prove far more successful if access rights questions are not handled as functions of user or process state. In "closed" process monitoring and control systems, such mechanisms are made available as system services.

Of particular importance in process control engineering is the seamless integration of visualization design into the engineering process as a whole. This includes, for example, the linking of process visualization and dynamic process data generated in the design of process-level (local) components. Capabilities should be provided that make available the engineering data which indicates which process data are used in which visualization functions (design database).

Anticipated developments in graphics hardware for human – process communication are discussed below. Modern visualization systems intended for use as display and control components in process control systems are based on 2D graphics. Three-dimensional images can also be displayed on a 2D screen. The representation of the Space Shuttle in Figure 390 shows how hidden lines and surfaces can be removed from the three-dimensional picture by using computer graphics. However, mapping a three-dimensional model onto a two-dimensional surface (well-defined portion of the image, well-defined angle of view) places a considerable load on the computer that constructs the individual points of the image. Accordingly, 3D graphics on a 2D screen is severely limited in speed. Graphical representation capabilities in process control systems with modern 2D graphics systems are illustrated in Figure 376.

Figure 390. Three-dimensional representation of the Space Shuttle on a two-dimensional screen [765]

The performance of graphics systems is improving continuously. Graphics systems from the CAD realm and scientific data processing already hold an internal 3D representation, which they map onto the selected viewport. This implies a substantially larger graphics memory (a complex volume model, for example, requires 500 000 vectors, each represented by several bytes, so that the total memory demand is several megabytes). The enormously high performance required of graphics systems in these applications stem from close-to-reality graphical representation combined with animation capabilities. An example is the simulation of poor visibility in the training of aircraft pilots [767]. Graphics systems, usually implemented on a dedicated board or even as multiprocessor systems, can now plot up to 10^6 3D vectors per second. The workstation CPU and the graphics processors split the work up in a rendering pipeline [768]. Data transmission over an internal bus is a bottleneck, as in many other situations. Modern graphics workstations have main memory capacities of 16 – 128 MB and even more. The capabilities of modern high-performance graphics hold the promise of real-time visualization of complex data collections in n dimensions, a procedure that has now become the state of the art in scientific data processing. Isolines, textures, and other resources are used along with color to handle the n-th dimension or variant in graphical repre-

sentations. Photographs of glowing metal slabs or bars provide an example. From the color of a glowing piece of metal, it is easy to determine the temperatures of the individual zones. The color scale runs from white (highest temperature) to black (lowest temperature). In Figure 390, color is used as the fourth dimension in visualizing the temperature distribution of the Space Shuttle. Color can also be used to visualize other quantities such as height, material density, etc. The use of color as a supplementary element in graphics is advantageous chiefly in raster graphics, since colors can be gradated extremely finely in this kind of representation (high color resolution).

There have also been new developments in pointing devices. The mouse is now commonplace in office automation. In conjunction with the use of workstations as display and control components, it will be used in the process control room environment as well. Futuristic concepts of interactive devices go yet further: An accelerometer on the fingertip makes it possible to determine the direction in which the finger is pointing, and observation of the pupil tells where the operator is gazing. Electronic gloves equipped with sensors (datagloves) are already in use, chiefly for research and in virtual reality systems [769]. The first commercial applications have come about in the CAD field. In the n-dimensional data or feature space concepts discussed above, an operator using such an interactive tool can manipulate data and freely select a point for viewing images, thus wandering through the feature space.

Multimedia Techniques. Control and monitoring functions in process control systems have recently been expanded by techniques broadly referred to as multimedia. STEINMETZ has given a qualitative, application-neutral definition of this term [770]. The types of media supported and the options for media processing on a computer system are key features. Multimedia systems must be able to process discrete media (e.g., text and graphics) and continuous media (e.g., audio and video) independently of one another. The computer is extending its capacities to every medium by which information can be propagated and presented. The central points in multimedia are integration of media, range of media, distribution of multimedia information over a computer network, and user interaction with a multimedia system.

From the standpoint of information technology, crucial tasks for media integration are to create digital representations of the media, to develop suitable storage media, and to augment communications networks. The main problem is the high flow rate of time-critical multimedia data. For example, the digitization of a video sequence at normal resolution requires data rates of over 20 MB/s. Key technologies for implementation are digital signal processors for data compression, optical storage media, and high-data-rate networks.

Ultimately, multimedia systems make sense only if efficient system management insures the on-time processing of, in particular, continuous media. Requirements in this area apply to real-time processing in multimedia systems, specific service reservation, and the synchronization of linked information units or information streams relating to discrete and continuous media. Finally, the developers and users of a multimedia system should be able to operate in the way they have become accustomed to with discrete media. This means that multimedia functionality must be properly abstracted in development systems, user interfaces, and database systems. The object-oriented approach finds use here. Examples of the abstraction of multimedia capabilities can be found in multimedia add-ons to window-oriented graphical user interfaces running on personal computers and workstations. The desktop metaphor has been expanded to include, for example, a telephone, a dictating machine, and a video conference. These points will not be discussed at length here, nor will the associated problems, in particular the management of large bodies of data, diverse data formats, links between distinct media objects, and content-oriented searching. Reference should be made to the specialist literature [770–775]. In what follows, special requirements on the use of multimedia are presented, along with possible application areas in process control engineering.

Real-time requirements in process control mean that the correlation of data in a variety of media – especially continuous media – to objects, events, states, alarms, etc., is a central problem. Furthermore, because events in technical processes occur in stochastic fashion, it is impossible to predict at what time which multi-

media input/output devices need to be available. Conflicts, such as when several audio sequences must be output at the same time, must not occur, although it is entirely possible for the operator to be simultaneously occupied with several distinct tasks. These points can be traced back to the problem of multimedia resource management. A concept for the integration of multimedia in an information and diagnostic system for use in process control is proposed in [776]. A major role is played by the presentation system, which is responsible for synchronized input and output matched to system and user requirements.

Already common in the process industries is the use of cameras and microphones to monitor machinery, plant sections, and products. Generally, this involves self-sufficient analog monitoring systems with no connection to the process monitoring and control system, or else hybrid systems in which analog recording devices are controlled by computers through interfaces. In both cases, the data stream remains unprocessed and isolated from other information-processing functions. In digital multimedia systems of the future, integrated processing of all media will be possible. First, other information can be appended to audio and video signals (timestamp, links to process data, comments, etc.). The result will be new capabilities for messaging, reporting, and archiving systems. Second, digital image processing will offer new possibilities for human – process communication. Digital image processing is already employed in industrial robots (machine vision), in computer-aided quality inspection of finished parts, and in the monitoring of machinery [777, 778]. In human – process communication, digital image processing, perhaps in conjunction with CCD cameras, will provide a route to alternative methods by which product and process states can be determined and classified and the results presented in a visually informative way. An example is the assessment of temperature profiles in metal working by determining gray-scale distributions [779]. Finally, the operations of digital image processing have the goal of presenting the operator with visual information in an appropriate and easily remembered form. A closely related topic is pattern recognition, a set of techniques which permit the identification and grouping of logically like image contents and thus the identification of single objects [780].

In addition to the question of possible applications for multimedia systems, another point of interest for human – process communication is how these systems can be put to use. First of all, the modality – i.e., the way in which the operator's sensory organs take part in the interaction – of the operator – system interaction is expaned, for example by speech, but also by futuristic concepts such as the interpretation of body language [781, 782]. The objective is to make user interfaces more "natural" by letting them use a broader sensory spectrum. Information acquisition can be facilitated and supported through input and output in the original medium without transformation, as in voice mail, or through multimodal presentation of information in more than one medium. An application is the audio-visual notebook, in which video records with added comments provide information about special events.

A second system-related aspect is "active" user behavior. The pertinent concept here is hypertext or hypermedia [783], which is a concept for organizing and actively "exploring" information.

Essentially, a hypertext or hypermedia system has two components: networks consisting of elementary information units (nodes) and flexible, directed references (links), and tools for creating these networks, reading them, and so forth. Hypermedia differs from hypertext in that the nodes contain multimedia information. The user wanders through the network in survey fashion (browsing) or with a definite destination (navigation). The contents of nodes and links need to be static. The concept also includes executable code as well as the on-line determination of the destination of dynamic links as an aid to navigation. More complex structures can be generated by aggregating networks. For a more in-depth treatment and discussion of further aspects, such as programming and tool/system support, see [729, 784, 785].

The first applications of hypertext concepts came in the organization of documents in "information systems" (information kiosks) and in education. Hypermedia systems have found industrial use as technical information systems for commissioning, repair, and service documentation [786]. In technical processes, the operator of the future will obtain required knowledge, such as safety aspects, through information systems

of this kind. At present, work in this area is being carried on in a EUREKA project [787]. Hypertext concepts in human – process communication can also be put to work in on-line operator support or operator training systems, in particular systems that will guide the unpracticed operator to the correct control actions [788]. Similar considerations relating to ship steering are presented in [789]. Closely related to hypermedia concepts in process control is the linkage to knowledge-based methods; hypermedia systems are used as user interfaces for diagnostic systems, since operator behavior can be better supported with them [790] (see also Chap. 13).

Trend Forecasts. Instances of information-oriented process control engineering can be found today in aeronautics, the power-plant industry, and automaking.

Flying involves very complicated changes in attitude resulting from course changes. In modern aircraft, these trimming or dressing actions are performed for the pilot by a computer-supported control system. Thus the pilot can fully concentrate on determining the course, using a joystick to specify course changes to the autopilot, which in turn generates the control instructions needed to alter the attitude. In order to reduce further the cognitive burden on the pilot, aircraft such as the Airbus A310 include a display showing the instantaneous position with the planned course and a proposed course deviation. The justification for the deviation is incorporated into the display; for example, if it is an area of bad weather, a weather radar display is superimposed (Fig. 391) [791].

Similar developments are under way in automotive engineering. Navigation devices use graphics to display the position and the proposed course to the desired destination, taking account of current traffic conditions [792]. Required maintenance is determined by using models and reported to the driver; an example is the service-interval display developed by BMW [793].

Another example of information-oriented process communication is a display showing ignition angle plots for a digital motor ignition system [794].

In power-plant control engineering, the status of a boiler or turbine is displayed as an instantaneous operating point on a plot of characteristic curves. Any change in operating point can be effected by using a crosshair pointer to specify a new nominal operating point. Individual setpoints are then obtained from a process model [795].

New approaches to information-oriented process control engineering are also seen in the chemical industry. In general terms, product properties E can be represented as functions g of process properties P. This procedure is readily illustrated in process space (Fig. 392) [796]. For a certain product property E_0, there exists a function $g*$ of the process properties P_i and P_j, as shown by the curve. The thicker portion of the line characterizes the optimal re-

Figure 391. Airbus A310, navigational display [791]

Figure 392. Process space (two-dimensional)

gion for the process, characterized by compliance with additional constraints. If certain tolerances ($E_0 \pm \Delta E_0$) are set when the values of the product properties are established, then in the process-space representation this corresponds to a certain variation range of the process properties (shaded region). In a specified technical apparatus, of course, the process properties can be varied only within certain ranges ($\Delta P_i, \Delta P_j$); the rectangle shown in the figure is obtained as a result. Safety and environmental restrictions narrow the acceptable region of the process space still further, leading to the areas enclosed by dashed lines in the figure.

Figure 393 shows another way of thinking about a real process. In process space (normally the coordinates are configuration parameters determined by order reduction), the hatched region shows the normal production condition for a certain product. The white rectangle located on this is the economically optimum operating region. The variation in the process properties allowed by a specified apparatus is indicated by the outline of a parallelepiped. The upper and lower gray areas show the restrictions imposed for safety and environmental reasons.

Figure 393. Process control with the joystick

Figure 393 also shows how the operating point on the screen can be moved into the target region, for example with a joystick. The change so specified is then automatically transformed to setpoint (control) signals [797].

Tracking the operating points in a process as just described indicates the distance from critical regions and, eventually, may also make it possible to initiate prompt computer-aided action to remedy disturbances. The analytical preconditions for doing this have long been known from fault-tree analysis.

Another type of process communication can be implemented with the help of Wolf diagrams [798].

These examples from a variety of technical application areas suffice to illustrate the present and foreseeable capabilities of information-oriented communication.

Information-oriented process control engineering will relieve operating personnel of some burden, help them avoid errors in disturbance situations, and promote the optimization of processes through improved modeling. This innovation will also make it easier to produce better and more consistent quality in accordance with specified nominal profiles. The operating personnel will be able to put more effort into studying the process as a basis for modeling. Furthermore, it will be possible to employ operating personnel with a broader spectrum of skills, and at the same time the monotony of continuously watching single signals will be broken up. Finally, the early detection of incipient transitions to undesirable operating states will lead to improved operational safety and reliability.

These are all good reasons for supporting information-oriented process control engineering. "Signal-oriented" process control engineering, which recognized only human – machine and instrument – machine modes of communication, will be replaced by "information-oriented" process control engineering, which includes the concept of human – process communication.

11.3. Process Analysis and Process Optimization

In 1984, Blass [799] proposed a method that requires a methodically structured procedure in the development of complex systems so that a clear, comprehensible framework can be obtained for the application of specialist knowledge and creativity and the range of possible approaches to finding a strong solution can be developed and exhausted. The method of choice should always be a systems approach, which furnishes methods, principles, and proven resources in a relatively abstract and easily interpreted fashion, in the form of the system concept, the systems procedure, and project management.

Nevertheless, there are still processes whose development has not had the benefit of the

systems approach. Thus, retrospective methods were sought for determining the validity of existing processes so that they can be optimized.

An example is the electrophotographic reproduction of images, for which BIXBY [800] and BICKMORE [801] found an approach that involved breaking complex processes down into steps and interpreting these in physical, chemical, and process-engineering terms.

Figure 394 shows how the transfer process can be analyzed into single, physically comprehensible steps and how information can be gained in this way about the overall process.

Figure 394. Analysis of the electrophotographic copying process into steps [800, 701]

This representation, often called a Jones diagram [802], is an effective way of taking individual transformation operations into account and converting object information into pictorial form [803].

Transfer Theory and Transformation Principle (see Chap. 2). Any optical copying process has the task of transforming the optical density distribution of the object $T(x)$ to an optical density distribution of the image $D(x)$. This process is described by transfer theory. Let the object $T(x)$ be expressed in terms of spatial frequencies R by the Fourier transform method:

$$T(x) = \int_R h(R)\, \mathrm{e}^{2iRx} \mathrm{d}R \qquad (11.3.1)$$

The frequency R denotes lattice periods per unit length. The image $D(x)$ is then represented by

$$D(x) = \int_R K(R)\, h(R)\, \mathrm{e}^{2iRx} \mathrm{d}R \qquad (11.3.2)$$

where $K(R)$ is the modulation transfer function (MTF), generally a complex-valued function. Its modulus describes the contrast with which the sublattice of frequency R is transferred from the object to the image.

The advantages of formulating the imaging process in this way is that the transfer fucntion collates all the properties of the transfer system in a single function; by multiplication of further transfer functions, processes can be represented in simple form and complicated processes can be broken down into steps.

At a high level of abstraction, profiles of product properties (Fig. 360) can be compared to optical density (blackening) distributions. Each process element then indicates (as discussed in Chap. 2) how each element of the product property profile is transferred to a new element, namely a property element of the end product, by a process step or process segment.

The analogy to the concepts advanced by GILLES [684, 804] and POLKE [805] is then logical.

In this relatively simple procedure, in which the modulation transfer function plays an effective modeling role, it was possible to describe and analyze the individual physical operations in the complex copying process. Later, the term "process analysis" was introduced [806] for quite different processes, such as the vulcanization of rubber. Existing processes were examined, from starting products through all process steps to end products, including the operational logistics, technical equipment, and process control engineering.

The entire process, the plant, and also the operational surroundings are thus examined with the objectives of separating dependent from independent variables; identifying possible improvements on the basis of the relations found; and devising and utilizing new – and possibly unconventional – solution approaches.

Figure 395 shows the material and data flows in a process, and Figure 396 shows the same relationships for the example of a vulcanization process. As early as 1972, a "process indicator," a

Figure 395. Process analysis (material and data flows)

Figure 396. Process analysis (rubber vulcanization)

precursor of the model-aided measurement technique [807], was in use.

When there are obvious weak points in the operation, improvements are often carried out by taking single actions based on day-to-day experience. Such improvements have to do with the optimization of a unit operation, a plant section, or a single apparatus. Along with the advantage of solving the problem relatively quickly, this procedure has the drawback that the real cause of the problem remains undiscovered and substantial potential for improvement remains unexploited. As a rule, therefore, process analysis must always be performed from a holistic point of view so that improvements throughout the process and the plant can be effected. Finally,

process analysis is a tributary activity of process development (see Fig. 416).

The first step in a process analysis is to break down the overall process into individual process elements in such a way that the product property changes brought about by each element are covered by the phase model described in Chapter 2 (see Fig. 33).

As stated above, the transformation principle of Chapter 2 is used extensively (see also Fig. 417).

These relationships were also pointed out by Rumpf, though he used a different vocabulary, speaking of property functions in the course of the process [804].

This fundamental insight into the holistic analysis of a complete process is reinforced when process control systems are employed; very much more than previously, these presuppose a thorough knowledge of the process. This point was made in 1979 in the documentation of a correspondence course published by the Chamber of Engineering of the German Democratic Republic [808]. The form description of the dependent variables in a production process, of the product properties, as a consequence of the variation of the independent variables, of the process properties, has since come to be referred to as modeling (see also Chap. 3).

Here, the problems of process analysis are treated from the viewpoint of the process control engineer, who must acquire knowledge about the controlled process from the process engineer, the designer, the equipment fabricator, and others; that is, from the people who have the main responsibility for designing the apparatus, the facilities, and the processes to be run there, and whose work therefore must precede as well as supplement that of the process control engineer. This applies, in particular, to the analysis and description of processes in a form that is usable by the process control engineer and accessible to his methods and procedures.

The result of such a process analysis with a process control engineering orientation, however, not only provides the process control engineer with information about the process but also provides the process specialist with pointers on the active design of the process. This specialist is then better able to develop the process from the outset in such a way that it lends itself to the process control engineer's approach. This will greatly facilitate the design of the process control system. The outcome of such a process analysis can also be a considerable aid in the commissioning and maintenance of the plant [808].

The restriction to a process-control orientation of the process analysis has the result that the informational context becomes a key factor in the analysis. The work of Blass [799] has set the direction for the overall aspect of process analysis, which must always be kept in mind even when dealing with details. Together with presentations at the annual conferences of the VDI Association for Process Engineering and Chemical Engineering (GVC), Blass' publications provide an ever-fresh source of new methodological and technical information [809]. Blass also stresses the need for heuristic procedures, especially in engineering and scientific fields.

For this reason, what follows is a presentation of one such method that has been tested in practice, both for process analysis and for process development [683, 810].

Under certain conditions, product properties and process properties can be plotted as points in appropriately defined mathematical spaces. Some mappings between these spaces can be interpreted as production models that permit the formal mathematical description of product development in terms of process variation. There are tools, many of them tested in the field, for implementing this generally valid concept [683].

A company that wishes to succeed in the market must adapt the quality of its products to the requirements of the market. This adaptation can be interpreted as a measurement and decision problem.

The properties of the products produced by the company and required by the market should be quantifiable and their relative separation should be measurable. In principle, this objective can be achieved by reducing all "technological" properties to physical ones [806]. The physical properties assigned to a certain product are then interpretable as a point in a metric space. The nearness of the product quality to a required level can be objectivized in this way. The process of deciding whether product or process development should be carried out thus becomes transparent.

The question with what resources a quality improvement can be effected is first of all a question of operational capabilities: With what

Figure 397. Factors affecting product quality (left) and market requirements (right)

processes are the current products made? Will changes of recipe in the context of existing processes result in the desired quality changes, or will process modifications or even new process development have to be carried out.

An analytical approach here affords some help in ordering the operational reaction possibilities. If a process is represented in terms of the set of assigned and independently variable process properties, then in analogy to the product space these span the process space, in which a metric is defined (provided the properties are measurable). A recipe is a certain expression of all the properties characterizing the process and can thus be interpreted as a point in this space (process state; see Fig. 388).

Now product development can be carried out in a controllable manner if it is possible to construct a mapping that assigns points in process space (recipes) to points in product space (product qualities). It is shown how the relationships between these spaces must be utilized in order to achieve product development through process variation.

It is further shown that process optimization, viewed from the standpoint just developed, generally reduces to a variational problem with constraints. The mapping from process to product space describes, in model terms, the interaction between plant and product during the production process. Accordingly, this mapping can also be used as an aid to solving control problems. The importance of such process models for the construction and utilization of technical information and control systems, as well as for the solution of automation problems with the aid of modern computer systems in the chemical industry, should be expressly reemphasized in this connection.

Product and Process Properties (see Section 2.3). The market exerts a variety of influences on product development. For example, consumer habits change over time, often because of changes in the priority of their needs [811]. New technologies in the converting industries impose other (usually more stringent) requirements on products. The market demand for products with novel or improved properties can also be triggered by the appearance of competing products (Fig. 397).

The company, for its part, offers to this market products whose properties are governed by the raw materials and energies used, the number and skills of the operating personnel, and by the technological condition of the apparatus available. Figure 398 illustrates the decision problem arising from the situation just described. If the existing properties of the products made by the company are no longer adequate to satisfy the needs of the market, the company must decide whether to risk the loss of competitiveness or to react to the new situation by undertaking product and/or process development. To render this decision process objective and intuitive, it is useful to define the "properties" of the products more exactly, on the one hand, and on the other to quantify the company's ability to react ("process") [810].

Product Properties. Beginning with the idealization that product properties can be measured directly and immediately, every product property can be plotted in a histogram, along with its tolerance range, and the full histogram can be interpreted as the property profile (Fig. 399). In a number of studies [812–819], this method has proved extremely helpful in the analysis of requirement and qualification profiles (see also Fig. 400).

Applying this idealization to the concept of product properties often reveals the practical difficulty of relating distinct characterizations of one and the same property as determined by subjective assessments. In principle, of course, even the "technological" properties can be reduced to

Figure 398. Decision problem for/against product development and/or process development

physical ones, measured, and mapped on metrical scales. For this to happen, however, the usually complex relationships must be elucidated, and only in a few cases can this be expected. The assessment problems arising here are not dealt with further; reference is made to the literature [820] and to Figure 40.

Figure 399. Plot showing qualification profile and requirement profile

If the treatment is initially limited to the case where all properties are measurable, at least one distance function is found that satisfies the conditions for a metric. Let E denote the set of product properties and d the distance function; then the ordered pair $\{E,d\}$ is a metric space. In accordance with standard mathematical practice, the distance measure is immediately dropped from the symbol and E is referred to as the product property space. The concept of "space" can be retained even when there are nonmetrical types of attributes, provided the distance concept is suitably generalized (e.g., topology and separation axiom → Hausdorff space).

As a rule, the property profile of a product includes redundancy. An analysis of the deterministic and/or statistical relationships of the profile leads to a reduction in the number of attributes needed to describe the object "product." This process is briefly described in Figure 401 and illustrated in Figures 402 and 403.

The result is that any product property profile can, with the aid of the concepts just developed, be treated as a point in a suitably selected product space. These concepts also make possible an exact definition of the hard-to-pin-down term "quality": Quality is a point in product space. If the components of the profile are also linearly independent and their realizations can be plotted on the real axis, then the property space is a vector space over the real numbers, and any profile can be interpreted as a vector in this space. Tolerances of the individual product properties allow the point to grow into an elementary volume (Fig. 404; see also Fig. 389).

Process Properties. A "process" is the operation of creating products having certain properties. Its operationalization leads to the elements of the process profile, the process properties P_j. A given realization of all the quantities characterizing the process (e.g., state variables, parameters, control variables, etc.) is called a process state. By construction, so to speak, all relevant

Figure 400. Qualification profiles of electrical engineers in process control engineering [817]

Reduction in number of independent components of profiles by identifying

a) deterministic relationships
b) statistical relationships

Examples	Relationship	Explanatory value
Electrodynamics	Physical theory	High
Diffusion equation	Semi-phenomenological model	↓
$J = \sigma E$	Empirical model	
$\gamma = \alpha + \beta x$	Regression model	Low

Figure 401. Analysis of product property profile (see also Section 3.4)

process properties involved in process development and plant design will be measurable (monitorable). In canonical fashion, the independently variable process properties span a vector space. By analogy with the product property profile, a recipe can now be interpreted as a point in the process space (Fig. 389).

Since the region of definition (range of variation) of each process property in real systems is an interval of finite length, in analyzing a particular plant the treatment can be restricted to a finite region in process space. All that is necessary is to replace E_j by P_j in Figure 404.

Product and Process Development. The entire production process is handled as a successive transformation of product property profiles (see Section 2.3). A process, specified by the process properties and represented by a point in

Figure 402. Correlation between components of the product property profile

Figure 403. Functional dependences between components of the product property profile

process space, maps an initial property profile to a final property profile and thus links two points in property space. Now the procedure of "product development by process variation" can be formally represented as a function

$$F\,[P_1, \mathrm{P}_2, ..., P_j; E_1, E_2, ..., E_i; E_\mathrm{A}] = 0 \qquad (11.3.3)$$

where P_j are the process properties in process space, E_i are the product properties in product space, and E_A denotes the initial product properties upstream of the process (see also Figs. 360 and 417).

Figure 404. The product property profile as a multidimensional vector in product space

After these general preliminary comments, the particular question of concern in this discussion – the form of the product property profile – comes to the fore. The initial profile is taken as given and fixed. Equation (11.3.3) then depends on the variables P and E. If the market now demands from a product a certain nominal property profile E_S, this has its formal expression in the condition:

$$g\,(P_j) = 0 \qquad (11.3.4)$$

where g is specified by the initial property profile E_A and the nominal property profile E_S and by the interaction of plant, apparatus, and product taking place in the process step under examination.

Specifying one fixed property profile (a point in property space) reduces the number of degrees of freedom in process space by one. The set of permitted product states then lies on a hyperplane in process space (Figs. 405 and 406). After this analysis of the relationships between product and process spaces, an attempt is now made to answer the question of how a product property profile imposed by the market can be realized with the company's resources, taking both safety and economics into account.

Interpolation. In the first step, this objective is to be achieved and the possible experiential horizon of an existing plant is to be exhausted.

Figure 405. Initial product property profile E_A and nominal product property profile E_S as points in product space

Figure 406. Hypersurface of property-equivalent process states in process space

A "recipe change of the first kind," which does not lead out of the original hyperplane in process space (Fig. 406), does not change the product properties (Fig. 405); such a change is therefore ruled out if the required profile E_S and the initial profile E_A are different. If, however, one moves off the hyperplane ("recipe change of the second kind"), products are now obtained with new property profiles (Figs. 407 and 408).

If one of these points lies sufficiently close to E_S, product development can be regarded as successful and no plant change is required.

If the requirements imposed cannot be satisfied in the context of the existing capabilities, the initial experiential horizon in process space must be enlarged.

Figure 407. Property-changing process-state variations with no modification of plant

Figure 408. Possible property changes after the action described in Fig. 407

Figure 409. Property-changing process-state variations with modification of plant

Figure 410. Possible property change after the action described in Figure 409

Extrapolation. In a second step, this is to happen while the dependences in process space are preserved. The same set of process properties are selected as above. If, in the development of products with new properties, the ability to produce the original assortment is to be preserved, then the range of variation of the individual process properties must be expanded by constructive actions. If the strategy requires the substitution of individual products in case of (partial) abandonment of the original assortment, subsequent process development comes down to generating a new range of variation of the process properties (upgrading, "reboring," debottlenecking).

Figures 409 and 410 illustrate this extrapolation step. If such an extrapolation does not lead

Figure 411. Hypersurface of property-equivalent process states in the new process space generated by process development

Figure 412. Possible property change after the new process development described in Fig. 411

to the target, the experiential horizon must be expanded in a third step by development of a new process or a new plant.

Under some circumstances, this leads to new relationships in process space (Figs. 411 and 412). It remains valid that a hypersurface (generally of a different nature) in process space corresponds to the (desired) property profile.

Optimization. Subject to the condition of generating equivalent property profiles, all process states on the respective process-space surface are equivalent. This fact can now be used in selecting a process state optimal with respect to the extremalization of a target quantity (cost, energy consumption, yield, etc.). From the mathematical standpoint, this commonly reduces to a variational problem with constraints (Fig. 413).

Figure 413. Optimization of the process with respect to a goal quantity

Noted that the concept developed above makes the actions to be taken in product development by process variation, as well as the way of evaluating their success, more intuitive, and also makes it possible to check them step by step (see also Figs. 414 and 415). However, a certain effort must be taken in order to prepare the required tools.

The question whether product development is necessary is thus answered by comparing the qualification profile E_A and the requirement profile E_S of the marketed product, that is, by deciding whether the existing properties of the product correspond to the properties required by the market.

Figure 414. The product property profile as a function of time

Figure 415. Dynamics of process development can be traced in product space: the portions of surfaces represent sub-goals of development

If the qualification profile and the requirement profile are in agreement to a great ex-

tent (that is, if the point in product space does not change), then a merely desirable improvement in the result does not demand any product change; if the process structure remains the same, however, itwill be useful to optimize the possible changes in process properties (top row in Fig. 416) without moving off the equiproduct surface (see also Fig. 413).

	Point in product space	Point in process space	Process structure
Process optimization	does not change	changes, stays on equiproduct surface	remains unchanged
Product modification	changes slightly	moves off equiproduct surface*	remains unchanged
New product development	changes greatly	moves off equiproduct surface	changes

*The equiproduct surface is the locus of all process property profiles that lead to the same product property profile.

Figure 416. Process/product variations

A product modification required by the market can be effected in either of two different ways:

- If the requirement profile is close to the qualification profile, then it is generally possible to continue working with the same process structure. For a product modification, the process properties are changed within the technically possible range of variation, but this necessitates moving off the equiproduct surface (middle row of Fig. 416).
- If the requirement profile and the qualification profile of the desired product are far apart, then as a rule it is also necessary to change the process structure, that is, carry out a new development (bottom row in Fig. 416).

Measures for Realization. *Production Model.* The material flow of a typical multistage production process in the chemical industry (phase model) is shown in Fig. 360). By abstraction with the aid of the concepts developed above, this material flow is mapped onto an information flow. The elements of the product space are described by the product properties and the points in the process space correspond to the process properties. Further details can be found in [807] and Figure 417 (see also Sections 2.3 and 3.5). Figure 418 shows how the information acquired can be utilized to discover the explicit relationships between plant, machine, apparatus, and product (i.e., between the process properties and the process) for each process step.

Figure 417. Ideal and real models of production (phase model)

In particular, methods of "system identification" make it possible to derive statistical process models from production data. Such models are needed for tasks in process control engineering (e.g., process indicators [806], observer model). Multivariate methods (such as factor analysis, cluster analysis, and analysis of variance) make it possible to establish functional relationships between process data and quality data (see Section 3.2).

In summary, it can be stated that the central objective of any process analysis and process

optimization is to achieve reproducible nominal product properties. Naturally, the first step is to describe with care the product properties, from the beginning up to the end of the entire production process, and of course also for each intermediate step. The creation of the phase model as shown in Figure 416 is therefore the central task of the process technologist. A holistic viewpoint is of fundamental importance (see also Chap. 10). This information-technical step is the most important task.

Figure 418. Evaluation system for quantifying the relationship between process and product properties (see Section 3.2)

Execution planning, execution, and quality assurance are described in depth in Chapter 10. They are to be applied, with appropriate modifications, to the problem and task discussed here.

Process analysis and thus process knowledge are also necessary conditions (as shown in Section 11.2) for state-oriented human – process communication so that the production process can be managed and controlled at all times and under all conditions.

11.4. Maintenance Strategies

Introduction. Before maintenance strategies are discussed, the key objectives of maintenance should be defined [821].

Production facilities are used for making consumer goods. During this production process, the facilities wear out in various ways. In order to remain functional despite wear, production facilities have a reserve of possible function fulfillments, called "wear-out reserve," which is gradually diminished during service (Fig. 419) and ultimately leads to breakdown.

Figure 419. Wear-out reserve versus time

In the nominal condition, the production facility has a 100 % degree of function fulfillment. After a certain time, it loses its wear-out reserve. The production facility remains operable, however, over a broad range.

The objective of maintenance is to keep the wear-out reserve always above the "damage limit" in order to prevent breakdowns. Maintenance includes three activities [821]:

- Routine maintenance to preserve the nominal condition
- Inspection to measure and assess the actual condition
- Corrective maintenance to restore the nominal condition

It is recommended that corrective maintenance be subdivided into scheduled maintenance and forced repairs (unscheduled maintenance) (Fig. 420).

This distinction relates solely to the management of maintenance work, not to the quality of the work. In the case of unscheduled maintenance, including forced repairs, the schedule

Figure 420. Scheduled and unscheduled maintenance

is dictated by the event, and the maintenance action is generally predetermined as well. The maintenance worker can thus do nothing but react. In the case of scheduled maintenance, the sequence of actions is determined in advance by the maintenance worker himself, who also influences the actions taken. In other words, the worker can take the initiative. Naturally, it is an important goal to put as much maintenance as possible into the "scheduled" category.

Maintenance will become even more important. The reasons are the increasing complexity of plants, the greater depth and breadth of automation, the growing size of production facilities, and the increasingly stringent requirements imposed on product quality, safety, and environmental protection.

Modern maintenance practices for process control and automation systems are discussed in [679].

As the tasks of maintenance change, its objectives also change. The goals of a maintenance organization have been stated as follows [822]: To guarantee the retention of value and functionality of production facilities while insuring compliance with requirements relating to

- Increasing safety and quality levels
- Reliability of on-time performance
- Economically optimal operation

Only when objectives have been clearly formulated can the "correct" strategies be identified and embodied in company policies so that economy measures in the maintenance area do not cause certain maintenance tasks to be neglected.

It is the increasingly high required safety and quality levels that mandate a change of priorities in cost-reduction strategies. Two common cost-reduction practices are

- Economical performance of maintenance activities
- Optimization of material and supply use in maintenance

But the potential of these has been largely exhausted. Now a new requirement has taken on top priority: reduction or even prevention of maintenance.

This practice, which involves the elimination of weak points, still holds a substantial potential for improvement. Production facilities needing fewer repairs have higher availability and can be operated both more economically and more safely. Finally, "maintenance" in a holistic sense has become a topic in the design process (Chap. 10) and must be considered at that stage.

Strategies for Performance of Maintenance Activities. Maintenance strategies serve to make maintenance a more systematic operation. They are oriented toward maintenance activities (Fig. 420). One speaks of a certain maintenance strategy, say an inspection-oriented strategy, if this activity (inspection) is purposely emphasized in the context of changing objectives and is not sacrificed when economy measures are introduced. Naturally, this does not mean that other maintenance activities are wholly de-emphasized.

Breakdown Strategy. The dominant role in the past was played by the breakdown strategy, which is based on forced repairs and, by definition, unscheduled maintenance. Despite the high

cost of devices used in process control engineering, this strategy is still fairly important because many of the sensors and actuators come into contact with products and hence experience contamination, deposits, plugging, and corrosion. It can be shown statistically that such breakdowns are not greatly reduced by more intensive scheduled maintenance. Some improvement is gained with measuring techniques, such as radiometry, that do not involve contact with the product.

Indeed, the breakdown strategy does have advantages: It entails low costs, the work can be done on site by foreman/craft teams, and downtime is generally short.

However, some significant drawbacks have also emerged:

- Costs increase with increasing degree of plant utilization and investment level
- Because of the "workshop" orientation, it may take much effort and expense to maintain operation at weak points such as those resulting from interaction with products; this strategy thus achieves the exact opposite of maintenance prevention
- More stringent requirements on safety, occupational health, and environmental protection, coupled with heightened public sensitivity, mean that a breakdown maintenance strategy cannot be practiced exclusively

Scheduled maintenance strategies have thus become more important.

Preventive Maintenance Strategy. Much was expected of preventive maintenance when scheduled maintenance strategies were first introduced. It is not just a matter of cost that has made this approach obsolete. The reliability of many devices (service lives of valves and motors) today is so great that preventive maintenance is justified only where an element wears out after a known time and can then be replaced as a unit, for example in the case of fluorescent tubes. Preventive maintenance is still necessary when there are special factors, such as plant safety or quality assurance considerations.

Inspection-Oriented Strategy. As safety and environmental requirements grow more stringent, the inspection-oriented strategy has come to play an important role. This applies to many devices significant for damage prevention or limitation, such as rupture disks, leakage retaining vessels, and protective and damage-limiting devices in process control systems. Legislation, such as the Störfallverordnung in Germany [Accident Regulation], mandates the continuous surveillance (inspection) of such devices in the form of periodic function checks. The performance and results of these actions must be documented.

These requirements have had dramatic effects. As a one-time engineering cost, they have given rise to extensive safety analyses with plant upgrades and danger aversion plans (e.g., functional inspection charts). More importantly, they have led to continuing additional labor costs for plant monitoring and safeguarding and for the documentation of actions carried out (see Section 3.5).

The specific cost of monitoring and documentation may decline over a span of years as new and improved inspection methods appear on the market. These might include instruments with automatic self-testing and auxiliary diagnostic devices in electronic systems (see Chap. 5), as well as model-aided early fault detection methods (e.g., [823]).

Another type of inspection-oriented strategy, visual inspection, is the basis for determining and assessing the conditaqtion of production facilities and process control equipment. The "preservative register" is a suitable technique for documenting the results [824].

Depending on the economic and political situation, another strategy may gain in importance: Maximization of plant availability, and thus safety, by application of the redundancy principle, as is already required in nuclear power plants [825]. The redundancy principle requires installation of spare devices, which automatically take up the function of broken-down units and report the malfunctions. This is not, however, a typical maintenance strategy but rather a practice that must be adopted at the design stage (see Chap. 10).

High availability, such as is achieved under the redundancy principle, improves the operating economics. The application of this principle leads, however, to higher costs, at least initially. Additional investment is required, which in turn gives rise to additional maintenance costs, since the redundant units must also be kept operable even when on standby status.

Scheduled Corrective Maintenance Strategy. The analysis of strategies would not be com-

Figure 421. The maintenance control loop [822]

plete without the strategy of scheduled corrective maintenance. Scheduling corrective maintenance (repairs) does not have the aim of restoring the nominal condition; instead, alternative solutions must be sought, with an eye to economic, ecological, and process-engineering considerations. The following question must be examined: maintenance, investment, or both? This applies to plants, plant sections, apparatus, and process control equipment. The procedure, also referred to as "intelligent" maintenance, regards maintenance in the context of the plant economy, that is, holistically. The "plant economy" includes

- Design
- Fabrication, installation, setup
- Use (operation, maintenance, upgrading)
- Replacement

The centerpiece of the method is a decision model that provides a sort of value analysis to support decisionmaking about maintenance practices. On the basis of a situation analysis covering certain independent variables and constraints, the technique compares alternative actions and rates them through cost – benefit analysis. Decisionmaking is not, however, automatic; an educated interpretation of events is needed.

Maintenance Control Loop. Maintenance is concerned with the actual and nominal conditions of the facilities and equipment being maintained. Maintenance can thus be regarded as a control loop, as illustrated in Figure 421, which shows a breakdown of maintenance activities. Findings, damage, and malfunctions must be acquired and evaluated; weak points must be iden-

tified by a process of closing in. Finally, the loop must generate actions, which function as control actions. They react on the facilities being maintained (except for unschedulable breakdown maintenance).

In the maintenance control loop, planning (design) work is an essential component of the plant economy. It is at this stage that maintenance costs are set by the choice of process and plant design. Planning yields the plant and device documentation, which serve as controlling data, but the working plans for scheduled maintenance can also be generated in this stage. Maintenance-oriented installation is crucially important, along with the maintainable design of apparatus and equipment (see Section 3.5 and Chap. 10).

A holistic maintenance program requires the support of a powerful information system. Maintenance-relevant information stems from all maintenance activities. The documentation, however, must focus more on movement data generated on site by the operating engineers in the course of their work. This information goes into object-related history files, which can then provide the informational basis for documenting maintenance activities or analyzing weak points.

Figure 422. Use of cluster analysis to identify weak points in a process control system

Figure 422 illustrates the identification of weak points in process control systems. The ordinate is the total time spent in remedying problems, and the abscissa is the number of problems arising with individual objects in the system. Each entry characterizes one object. The weak points are located at top right. They stand out because of the large maintenance time requirement and the large number of problems. On the basis of the history files, the numbered groups can be formed by an computational technique called cluster analysis [826].

Outlook. Breakdown maintenance continues to play by far the major role in the chemical industry. What is lacking is the logical application of scheduled maintenance strategies. This has to do with a shortage of methods and tools with which a maintenance program oriented chiefly toward preserving and restoring produc-tive capacity can be conceptually and informationally integrated into the plant economy. There are, however, difficulties in achieving this kind of integration; the staggered and often uncoordinated adoption of information technology (hardware and software systems) has meant that bodies of engineering, administration, economic, and logistical data are mutually inconsistent. This underlines the importance of using the methods described above for structuring the plant economy, and only then implementing it technically (see Chap. 2).

In an integrated data processing system, maintenance should be a component of the plant economy with at least the following elements [823]:

1) A documentation system for the acquisition, structuring, editing, and storage of maintenance-relevant plant data
2) Planning and control systems for scheduled maintenance
3) A control system for generating action- and object-based cost and performance reports and calculating maintenance performance figures

A maintenance information system comprising these blocks should have compatible interfaces to other in-company data processing systems, especially to the production planning and production control, bookkeeping and cost accounting, materials records, and engineering subsystems (see also Fig. 20).

12. Standards, Committees, and Associations

12.1. Principles

The committees and associations that are either directly or indirectly concerned with process measurement and control are so many and diverse that it is impossible to present a complete list. This chapter merely indicates the points of concentration, functions, and objectives of the most important such standardization bodies.

What is Standardization? A clear answer to this question appears in DIN 820 Part 1; 01.86; Paragraph 2: "Standardization is the unification of material and immaterial objects for the benefit of the general public, carried out jointly and in a planned manner by the interested circles. It must not lead to a special economic advantage for individual parties. It promotes rationalization and quality assurance in business, technology, science, and administration. It contributes to the safety of persons and property as well as the improvement of quality in all areas of life. What is more, it contributes to good order and the dissemination of information in the specific area standardized. Standardization is practiced at the national, regional, and international levels."

Who May Create Standards? In Germany, only DIN and DKE are permitted to issue mandatory standards. Under the standardization agreement between DIN and the Federal Republic of Germany, May 5, 1975, DIN is to represent the standardization interests of the Federal Republic in regional and international standardization bodies. CEN and CENELEC European standards also become effective only after they have been published by DIN or DKE. IEC and ISO international standards can be adopted as national or European standards, but there is no obligation to do so.

German-speakers distinguish between the terms "norm" and "standard." Norms are always somewhat official, while standards are private in nature and represent agreement among certain groups. Both terms relate to technical specifications. In the case of a norm, such specifications are adopted by a governmental or internationally recognized standardization organization. Common usage, unfortunately, does not always maintain this precise distinction, and one often speaks of ISO standards. In the German sense, these are norms, since they are issued by ISO.

VDE and VDI standards (called "VDE-Bestimmungen" and "VDI-Richtlinien") do not have the status of norms in law. They are designated as the state of the art. The same applies to the recommendations and work sheets published from time to time by other bodies such as NAMUR, ZVEI, or VIK.

The purpose of these publications is to make results in science and technology known to a broad public as promptly as possible, since experience has shown that the issuance of norms is a very slow process. These papers generally become proposed norms for consideration by standardization bodies, are discussed among a broad public, and after some years appear in modified form as norms. The essential function of these associations is thus to create draft norms and evaluate draft norms.

Both norms and standards are described by the single word "standard" in American English. A "norm" in Germany (and many other countries) might be equated, quite roughly, to a mandatory standard or a standard embodied in a governmental regulation, while German "standard" might correspond to a "voluntary" standard. Standards issued by ANSI, ASTM, etc., are considered voluntary in the United States, but elsewhere they may be regarded as closer in legal status to "norms." The remainder of this chapter employs "standard" for both classes but provides clarification when necessary.

So-called industry standards are in essence neither standards nor norms, but successful products or specifications that have become established in the market.

Situation in the United States. The ISA occupies a dual position in the United States: As a technical-scientific organization (comparable with VDE in Germany), it not only takes part in the preparation of standards but also has the power to issue its own standards, having been granted this right, for the field of process control engineering, by the American National Standards Institute (ANSI; see Section 12.3).

Also deserving of mention is the Institute of Electrical and Electronics Engineers (IEEE),

which develops and generates international standards. Its publications, however, are not mandatory standards but recommendations.

Changes in the Standardization of Process Control Engineering. The 1980s saw a marked change in technology, from signal-oriented measurement and control to information-oriented process control engineering. Not only companies but also national and international standardization bodies have had to deal with this change.

While standardization bodies in the 1970s were concerned with embodying the state of the art in standards, in the early 1980s the emphasis changed to standardization in parallel with research. To lower research costs, a context for development was established in national and international standardization bodies.

The changes in technology and in standards emphasis also necessitated a new structure. This was acknowledged at the end of the 1980s when three new bodies were set up: IEC TC65 (Technical Committee 65 – Industrial Process Measurement and Control), DKE FB9 ("Special Area 9 – Measurement and Control"), and NAMUR ("Standards Working Group for Measurement and Control Engineering in the Chemical Industry").

12.2. Standardization Bodies and Other Organizations Involved in Standardization

The most important standards bodies for process control engineering, with their functions and objectives, are listed below:

CCITT. The Comité Consultatif Internationale Télégraphique et Téléphonique (International Consultative Committee on Telegraphy and Telephony) unites national postal and telecommunications organizations and has jurisdiction over telecommunications standards.

CEN. The Comité Européen de Normalisation (European Committee for Standardization) has the European national standardization bodies as its members. Together with CENELEC, it creates European standards and provisional standards.

CENELEC. The Comité Européen de Normalisation Electrique (European Committee for Electrical Standardization) includes European national standardization bodies concerned with electrical technology.

CEPT. The Comité Européen des Administrations des Postes et des Télécommunications (European Committee of Postal and Telecommunications Administrations) is the conference of European postal and telecommunications agencies.

DIN. The Deutsches Institut für Normung (German Standardization Institute) is the national institution that develops and adopts standards (mandatory standards).

DKE. The Deutsche elektrotechnische Kommission im DIN und VDE (German Electrotechnical Commission of DIN and VDE, VDE = German Electrical Engineers' Society) is the national organization that develops standards and safety provisions in the electrotechnical field.

ETSI. The European Telecommunications Standards Institute was established by European telecommunications agencies together with the EC Commission after substantial deficiencies had been revealed in the assimilation of standards in the telecommunications field. ETSI's task is European harmonization of standards for public-sector telecommunications services.

IEC. The International Electrotechnical Commission develops international standards in the electrotechnical field.

ISO. The International Organization for Standardization functions as an umbrella organization for nearly 90 national standardization bodies. In the interest of flexibility, ISO standards are formulated with many degrees of freedom and must be made more specific by lower-level institutions.

The *International Electrotechnical Commission (IEC)* was founded in 1906. Its membership includes more than 40 national committees, and the official languages are English, French, and Russian. The purpose of the IEC is to support international collaboration in all matters of standardization and certification in the electrical and electronics fields. It aims to achieve this by means of publications, recommendations, and international standards serving as models for incorporation into national legal codes. IEC standards serve manufacturers, consumers, research institutes, and governmental agencies concerned with international trade and electrical safety issues. Any country, without restriction, can be-

Figure 423. Structure of the IEC (simplified)

come an IEC member. Figure 423 summarizes the structure of the IEC.

The IEC Suborganization "Conformity Testing to Standards for Safety of Electrical Equipment" (IECEE) has the purpose of certifying products for conformity to IEC standards. The certification system applies to electrical devices used in the home, the office, and the workplace. For further information, see [828].

The IEC Technical Committee TC65, "Industrial Process Measurement and Control" (Fig. 424), has as its scope the creation of international standards for systems and elements of industrial process control, including batch and continuous processes, as well as the coordination of standards for measurement and control devices and systems. Subcommittee SC65A, "System Aspects," is concerned with standardizing generic aspects of systems, such as operating conditions, assessment of systems, functional reliability, and so forth. SC65B, "Devices," deals with standardization of devices and systems in the field, the switch room, and the control room. In SC65C, "Digital Communication," standards are developed for communications between subsystems.

The *European Committee for Standardization* (CEN) and the *European Committee for Electrical Standardization* (CENELEC) came into being in the early 1960s as regional standards bodies (Fig. 425). The membership of CEN/CENELEC includes the national standards institutes of all EC and EFTA countries. These institutes are also members of ISO (International Organization for Standardization) IEC (International Electrotechnical Commission).

CENELEC has the objective of harmonizing technical standards in Europe. In order to achieve these goals, the harmonization efforts of the Community are (under Article 100 of the EEC Treaty) to concentrate on solutions that establish binding criteria and make standards the basis for determining the technical details of products. Moreover, with regard to problems specific to new technologies, it is important that standardization at the trans-European level become effective at an early stage.

Publications created by the specialist activity of CEN/CENELEC and issued by CEN/CENELEC are called European Standards (EN), Harmonization Documents (HD), Provisional European Standards (ENV), or CEN/CENELEC Reports. European Standards and Harmonization Documents are referred to as "regional standards" in the sense of the ISO/IEC definition. The various publications differ in the following ways:

– The basic rule is to create European Standards, since it is important that the national standards of the member countries be identical wherever possible.

Figure 424. Structure of IEC TC 65

- Harmonization Documents are issued when the change to identical national standards is unnecessary or impractical, and especially when a unification can be achieved only by granting national variances.
- Provisional European Standards are planned standards for use on a preliminary basis.
- CEN/CENELEC Reports are intended to provide information.

The Vilamoura procedure has the goal of promoting collaboration between national committees on a regional level by decentralizing the earliest stages of work. All new intentions to standardize on the national level should be disclosed in detailed form, so that all members are acquainted with the content of the proposed project and can indicate their interest in active participation if they wish to do so.

"New intentions to standardize on the national level" means all intentions to standardize at the national level except for:

- Revision of existing national standards (see explanation below)
- Adoption of the results of CENELEC work
- Adoption of the results of IEC work

The results of national notifications lead to an EN, an HD, or an ENV. Notifications must be sent to all parties concerned (national committees, the CENELEC Secretariat, and the Technical Committee) for response. If no positive responses are received, the notifying national committee is free to develop a national standard.

The notification process for the revision of national standards is based on the assumption that the intention to revise is justified by the necessity of updating the standards. The revision of a national standard for the purpose of taking over an IEC standard, IEC provisional standard, or IEC publication, or for the purpose of bringing the national standard into conformity with an HD or an EN need not to be disclosed under this procedure.

Figure 425. Organizational chart of CENELEC

The Technical Committees of CENELEC are numbered to correspond with those of the IEC. The member countries of CENELEC are listed below:

- Austria: Österreichisches Elektrotechnisches Komitee (ÖEK) beim Österreichischen Verband für Elektrotechnik (ÖVE) (Austrian Electrotechnical Committee of the Austrian Electrotechnical Society)
- Belgium: Comité Electrotechnique Belge (CEB), Belgisch Electrotechnisch Comité (BEC) (Belgian Electrotechnical Committee)
- Switzerland: Comité Electrotechnique Suisse (CES) (Swiss Electrotechnical Committee)
- Germany: Deutsche Elektrotechnische Kommission im DIN und VDE (DKE) (German Electrotechnical Commission of DIN and VDE)
- Denmark: Dansk Elektroteknisk Komite (DEK) (Danish Electrotechnical Committee)
- Spain: Asociación Española de Normalización y Certificación (AENOR) (Spanish Standardization and Certification Association)
- Finland: Finnish Electrotechnical Standard Association (SESKO)
- France: Union Technique de l'Electricité (UTE) (Technical Union of Electricity)
- United Kingdom: British Electrotechnical Committee (BEC), British Standards Institution (BSI)
- Greece: Hellenic Organization for Standardization (ELOT)
- Ireland: Electro-Technical Council of Ireland (ETCI)
- Iceland: The Icelandic Council for Standardization (STRI), Technological Institute of Iceland

- Italy: Comitato Elettrotecnico Italiano (CEI) (Italian Electrotechnical Committee)
- Luxembourg: Service de l'Energie de l'Etat (SEE) (State Energy Service)
- Netherlands: Nederlands Elektrotechnisch Comité (NEC) (Netherlands Electrotechnical Committee)
- Norway: Norsk Elektroteknisk Komite (NEK) (Norwegian Electrotechnical Committee)
- Portugal: Instituto Português da Qualidade (IPQ) (Portuguese Quality Institute)
- Sweden: Svenska Elektriska Kommissionen (SEK) (Swedish Electrical Commission)

The EC Commission has therefore devoted special attention to the development of standardized test methods for verifying compliance with the standards. The ultimate objective is a European certification framework that would award a publicly recognized certificate to products that conform to the standards. The ECITI (European Committee for Information Technology Testing and Certification) is a body created by the EC Commission for the purpose of promoting the testing of standard-conforming products in Europe.

CENELEC always follows the principle of using the results of IEC work whenever possible and also of carrying out new standardization projects within the IEC when there is a prospect of accomplishing this within a given time span. In this way, multiple treatments of the same topic are avoided. The extensive collection of IEC publications and the continuation of standardization in the IEC are important components of this effort. With the information agreement of November 1989 and the cooperation agreement that came into force on January 1, 1991, the essential tools for further collaboration between IEC and CENELEC and their members were created. The cooperation agreement aims, above all, to accelerate the standardization process by causing a draft prepared on one organization level to be submitted for agreement simultaneously and in parallel on the international and European levels.

DIN. The German standards system deals with all technical disciplines. DIN standards reflect actuality and document the level of technical experience. Each standard is investigated with regard to its economic impact, and only those that are absolutely necessary are issued. DIN standards contribute to rationalization, quality assurance, safety, and understanding in business, engineering, science, and administration, and also among the public. DIN and its agencies serve as the national representation in international and European standards institutions (ISO/IEC, CEN/CENELEC).

DKE. DKE is the German organization that develops standards and safety rules in the field of electrical technology. DKE is dedicated to the safety of persons using electricity on the job, at home, and during leisure time. DKE is further involved in solving problems of environmental protection, answering consumer questions, and creating nuclear safety regulations. DKE has jurisdiction over the harmonization of electrotechnical standards within the European Community.

In Germany, mandatory standards can be created only by DIN or DKE. Each European Standard must be incorporated by all CEN/CENELEC members into their own standards system. EFTA countries that have decided against the European Standards are free of this obligation. Adoption requirements such as those that apply to EN and HD documents do not exist for ISO and IEC international standards. On the European level, ISO/IEC standards are subjected to a questionnaire procedure; if they meet with agreement, they are uniformly adopted in all EC and EFTA countries.

Results of the work of DKE are issued primarily under the titles

- VDE-Bestimmung (VDE voluntary standard)
- DIN-Norm (DIN mandatory standard)
- DIN-EN-Norm (DIN European Standard), with DKE number if applicable
- DIN-IEC-Norm (DIN – IEC world standard), with DKE number if applicable

DKE's "Special Area" 9 (FB9) bore the name "Measurement and Control" up through 1990 and was then renamed "Process Control Engineering." FB9 (Fig. 426) creates basic standards for industrial process control as well as specialized standards for the following application areas: process engineering, power plants, networks, buildings, pipelines, ironmaking and iron founding, mining, shipbuilding, instruction and training, and laboratory practice.

It is not the job of standardization bodies to carry out preliminary technical and scientific work. This must be done by the societies that cover the various areas (e.g., NAMUR, GMA, ZVEI). This function includes the development of technical concepts, technical and scientific groundworks for standardization projects, and engineering studies and assessments. The procedure of standardization in parallel with development can only become an effective aid to both parties when close cooperation is achieved between these technical societies and the standards bodies.

Figure 426. Areas of interest of DKE FB 9

VDE. The transfer of technical and scientific knowledge, as a service to all professional electrical and electronics engineers, is the first task of VDE. The spectrum ranges from historical aspects of electrical engineering, through occupa-tional and educational problems, to accident research, and the drafting of standards.

VDI. The transfer of technical and scientific knowledge is the primary objective of technical and scientific work performed by the Association of German Engineers (VDI). This is accomplished chiefly in the VDI specialist subdivisions.

An important emphasis in these subdivisions is the creation of standards documents known as *Richtlinien* (guidelines), which reflect the state of the art but do not have the legal status of mandatory standards.

VCI. Among the diverse committees and working teams of the Verband der Chemischen Industrie (VCI, Association of the Chemical Industry), the Engineering and Law Committee merits special mention. Through the "Measurement and Control" working team, VCI makes use of NAMUR specialist knowledge. This working team is identical with the governing body of *NAMUR* (see below).

NAMUR. The Normenarbeitsgemeinschaft für Mess- und Regelungstechnik in der Chemischen Industrie (NAMUR, Standards Working Group for Measurement and Control Engineering in the Chemical Industry; Fig. 427) takes in users of process control engineering (electrical, measurement, and control engineering) in the chemical and allied industries. It was founded in 1949 by BASF, Chemische Werke Hüls, DAG Troisdorf,Glanzstoff-Courtaulds,Henkel,Ruhrchemie, UK Wesseling, and Farbenfabriken Bayer. At present, NAMUR has 54 member companies, a third of them located outside Germany (in Switzerland, Austria, Belgium, and the Netherlands).

Activities of NAMUR relate chiefly to:

- Participation in the standards committees of DIN and DKE (in particular, DKE FB9, "Process Control Engineering")
- Participation and input in the creation of standards and specifications at the voluntary standards level (e.g., VDI/VDE-Richtlinien documents)
- Exchange of experience with process control devices, especially with newly developed instrumentation and other hardware
- Publication of NAMUR recommendations in all fields of process control engineering when no other standards exist
- Scientific support of technical journals
- Publication of NAMUR Status reports to document the state of the art in the field of process control engineering

Further details can be found in [224] and in [829].

VIK. The Vereinigung Industrielle Kraftwirtschaft (VIK, Industrial Energy Management Alliance) was founded in 1947.

The principal concerns of the Electrotechnical Committee are as follows:

- Exchange of experience

Figure 427. Organizational chart of NAMUR

- Influence on the preparation of devices suitable for consumer use
- Influence on the modification of VDE standards to conform with consumer requirements
- Influence on decreasing the number of designs
- Efforts to establish optimal conditions for accident prevention
- Attainment of economic benefit in the use of electrotechnical devices

This applies to electrical installations and systems in industrial power supply and production service.

ZVEI. The Zentralverband Elektrotechnik- und Elektronikindustrie e.V. (ZVEI, Central Federation of the Electrical and Electronics Industry) represents the interests of the German electrical and electronics industry in matters of economic and techology policy. ZVEI has the following tasks:

- To safeguard the common professional and business interests of its members before all agencies, in particular by cooperating with regulatory, economic, and other agencies and institutions and seeking to provide input to legislative measures
- To promote the general economic and technical development of the electrical and electronics industries

ISA. The Instrument Society of America (ISA) was established in 1945 in Pittsburgh, Pennsylvania.

It is a nonprofit organization active in the technology, science, and educational sector. Its concerns are with the theory, design, manufacture, and application of process control devices, systems, and computers. It issues the monthly International Journal of Instrumentation and Control (INTECH).

In the United States, the ISA made its name with an extensive training program and companion publications such as books, journals, software packages, videos, and CBT (computer-based training) packages. Moreover, ANSI (American National Standards Institute) has delegated to ISA the right to issue mandatory standards in the field of process control engineering. Valuable comments can be found in numerous ANSI/ISA standards sections.

12.3. Technical and Scientific Bodies

It is difficult and often impossible to distinguish between societies that are active in the standard-

ization field and bodies whose work is primarily technical and scientific. The emphasis for technical and scientific committees is on the sharing of experience in research and development, production and technology, training and continuing education, and safety. Such bodies can frequently be identified by the fact that they regularly organize high-level congresses. In this way they contribute to forming public opinion, and this in turn influences standardization.

In Germany, for example, the DVT unites a number of technical and scientific associations, such as DPG, DIN, GI, VDE, and VDI. Also important for process control engineering are GMA, Gesellschaft für Informatik (GI, Society for Information Processing), and Gesellschaft für Mathematik und Datenverarbeitung (GMD, Society for Mathematics and Data Processing), a public-sector research institution.

At the international level, there are a variety of national societies with special objectives. One such society oriented toward automation technology is IFAC; toward metrology, IMEKO; and toward the type testing of measurement and control equipment, the International Instrument Users Association.

DVT. The Deutsche Verband technisch-wissenschaftlicher Vereine (DVT, German Federation of Technical and Scientific Societies) includes about 100 technical and scientific organizations. It has the objective of analyzing high-level problems in science and technology and representing the interests of engineers and natural scientists in scientific, economic, social, political, governmental, and administrative circles. Its tasks include the promotion of applied sciences, the unification of common technical principles, the improvement of technical education, and cooperation in shaping legislation in the field of technology and technical management. The DVT regards itself as a link between members and also between the membership and business societies whenever technical and scientific problems are addressed.

AMA. The Arbeitsgemeinschaft Messwertaufnehmer e.V. (AMA, Data Sensors Working Group) is an association of manufacturing firms in the areas of sensor technology, sensor-based measurement and automation, and microsystems technology.

DPG. The Deutsche Physikalische Gesellschaft e.V. (DPG, German Physical Society) has the following objectives: to advance pure and applied physics, to bring its members and all physicists living in Germany closer to one another, to represent physicists as a body to other members of society, and to promote the exchange of experience among physicists in Germany and between them and their colleagues in other countries.

Notable special activities in the field of process control engineering are the conferences held by the Beratende Ausschuss der Industriephysiker (BAI, Advisory Committee of Physicists in Industry): the sensor technology conference in Münster and the automation conference in Bonn.

GMA. The Gesellschaft Mess- und Automatisierungstechnik im VDI und VDE (GMA, Metrology and Automation Society of the VDI and VDE) is active in measurement and control technology, automation, and process control engineering. The spectrum of related applications extends from the basic chemicals industry to the process industries, industrial and process engineering, energy generation and distribution, the automotive, transportation, and aerospace industries, construction engineering, medical technology, public utilities and waste disposal operations, and special applications in machinery, apparatus, and instruments.

Measurement and control, as a basic process-level technology, forms the basis for the functionally oriented, hierarchically structured field of automation and process control engineering. The principal points of emphasis in the action chain between process, automation system, and human being, as well as the higher-order, associative disciplines and engineering technologies, are communication, design, and simulation, together with information processing and, on this basis, the techniques of process operation and monitoring, automation equipment and systems, the technology of actuators and sensors, and also the dynamics of machinery and processes.

Areas of activity of the GMA:

- Exchange and evaluation of experience and information
- Holding conferences and lectures
- Cooperation with national and international bodies working in this field
- Stimulation and support of research

Figure 428. Organizational chart of GMA

- Publication and support of scientific journals
- Development of guidelines and other recommendations
- Sponsoring young engineers
- Involvement in education

National collaborations:

DGK	Deutsche Gesellschaft für Kybernetik
DGQ	Deutsche Gesellschaft für Qualität e. V.
DIN	Deutsches Institut für Normung
DKE	Deutsche Elektrotechnische Kommission im DIN und VDE
GI	Gesellschaft für Informatik e. V.
NAMUR	Normenarbeitsgemeinschaft für Meß-und Regelungstechnik in der Chemischen Industrie

International collaborations:

IMEKO	Internationale Meßtechnische Konföderation
IFAC	International Federation of Automatic Control

The organization of the GMA is shown in Figure 428.

GI. The Gesellschaft für Informatik (GI, Society for Information Processing) has as its objective the interchange of technical and scientific information in the field of "informatics" or information processing.

GMD. The Gesellschaft für Mathematik und Datenverarbeitung mbH (GMD, Society for Mathematics and Data Processing) is a public-sector research institution that uses basic research in the field of informatics to further the development of information technology and its applications. On the basis of wide-ranging basic research, conceptual work is performed and methods are devised that will lead to tools.

GVC. The VDI-Gesellschaft Verfahrenstechnik und Chemieingenieurwesen (GVC, the VDE Society for Process Engineering and Chemical Engineering) is the specialist organization of engineers active in process and chemical engineering as well as allied occupational groups. One of its central activities is the annual congress of process engineers. Its objectives are as follows:

- Sharing of technical and scientific experience
- Employment of specialist competence of the GVC technical committees
- Training and continuing education
- Collaboration with other institutions

– Social policy

IFAC. The International Federation of Automatic Control was founded in 1957 as a multinational organization. Its members are technical and scientific societies from 45 countries. Its objective is to support control science and technology in a holistic sense, that is, technically, physically, biologically, socially, and economically, both in theory and in practice. The task of IFAC is to support information exchange between national and international organizations active in the fields of automation and process control engineering. IFAC holds a world congress every three years; between congresses, it organizes symposia and workshops on special themes.

Figure 429 shows the organizational structure of IFAC.

Figure 429. Organizational chart of IFAC

IFAC is a member of the "Five International Associations Coordinating Committee" (FIACC), which also includes the following bodies:

– IFIP International Federation for Information Processing
– IFORS International Federation of Operational Research Societies
– IMACS International Association for Mathematics and Computers in Simulation
– IMEKO International Measurement Confederation

Member societies of IFAC by country are as follows:

– Argentina: Asociacion Argentina de Control Automatico (AADECA)
– Australia: The Institution of Engineers
– Austria: Arbeitsgemeinschaft für Automatisierung
– Belgium: Federation IBRA/BIRA
– Brazil: Sociedade Brasileira de Automatica (SBA)
– Bulgaria: National Council of Automation
– Canada: Canadian National Committee for IFAC
– Chile: Asociacion Chilena de Control Automatico (ACCA)
– China: Chinese Association of Automation, Institute of Automation
– Czechoslovakia: CSFR National Committee of Automatic Control
– Denmark: El. Power Engineering Department, Denmark Technical University, Lyngby
– Egypt: Egyptian High Committee of Automatic Control
– Finland: Finnish Society of Automatic Control
– France: Association Française pour la Cybernetique, Economique et Technique – AFCET
– Germany: VDI/VDE Gesellschaft Mess- und Automatisierungstechnik (GMA)
– Greece: Technical Chamber of Greece
– Hong Kong: The Hong Kong Institution of Engineers
– Hungary: IFAC National Member Organization – Computer and Automation Institute
– India: India Institution of Engineers
– Israel: Israel Association of Automatic Control
– Italy: CNR Commissione IFAC
– Japan: Science Council of Japan
– Kuwait: Kuwait Society of Engineering
– Mexico: Asociacion de Mexico de Control Automatica – AMCA
– Morocco: Association Marocaine pour le Développement de l'Electronique, de l'Informatique et de L'Automatique – A.M.A.D.E.I.A.
– Netherlands: Royal Institution of Engineers
– New Zealand: Institution of Professional Engineers

- North Korea: Korean General Federation for Science and Technology, Korean Association of Electronics & Automation
- Norway: Norsk Forening for Automatisiering (NFA)
- Pakistan: The Institution of Engineers
- Poland: Polski Komitet Pomiarow i Automatyki i Robotyki
- Portugal: Associacao Portuguesa para o Desenvolvimento da Investigacao Operacional – APDIO, CESUR-IST
- Romania: Comisia de Automatizari, Inst. de Cercetari si Proiectari Automatizari – IPA
- Singapore: Instrumentation and Control Society
- South Africa: South African Council for Automation
- South Korea: Korean Association of Automatic Control
- Spain: Comite Español de la IFAC
- Sweden: Kommiten Svenska IFAC
- Switzerland: SGA, Schweizerische Gesellschaft für Automatik
- Turkey: Turkish National Member Organization – Otomatik Kontrol Türk Milli Comitesi (TOK)
- United Kingdom: United Kingdom Automatic Control Council – UKACC
- United States: American Automatic Control Council
- CIS: National Committee of Automatic Control
- Yugoslavia: Electrotechnic Faculty, Automatics and Systems Engineering Division

IMEKO. The Internationale Messtechnische Konföderation (IMEKO, International Measurement Confederation) was founded in 1958. It includes technical and scientific organizations in 31 countries. Its objectives are as follows:

- To support international sharing of experience in science and technology for the development of metrology, manufacturing and design of devices, and application of devices in research and industry
- To promote cooperation of scientists and engineers
- To hold a world congress every three years
- To establish Technical Committees
- To organize symposia, workshops, etc., on special themes and to publish the proceedings
- To cooperate with other international organizations having similar objectives(see IFAC)

A list of Technical Committees follows:

TC 1	Higher Education
TC 2	Photonic Measurement
TC 3	Measurement of Force and Mass
TC 4	Measurement of Electrical Quantities
TC 5	Hardness Measurement
TC 7	Measurement Theory
TC 8	Metrology
TC 9	Flow Measurement
TC 10	Technical Diagnostics
TC 11	Metrological Requirement for Developing Countries
TC 12	Temperature and Thermal Measurement
TC 13	Measurement in Biology and Medicine
TC 14	Measurement of Geometrical Quantities
TC 15	Experimental Mechanics
TC 16	Pressure Measurement
TC 17	Measurement in Robotics

Member societies of IMEKO by country are as follows:

- Australia: Institute of Instrumentation and Control
- Austria: ÖVE-ÖIAV Fachgruppe Messtechnik
- Belgium: Belgian Measurement Confederation
- Brazil: Brazilian Association of Mechanical Sciences
- Bulgaria: Committee for Measurement of the Association of Science
- China: Chinese Society for Measurement
- Czechoslovakia: Czechoslovak Scientific and Technical Society – CSVTS
- Denmark: The Danish Society for Engineering Metrology
- Egypt: Egyptian Organization for Standardization
- Finland: Finnish Society of Automatic Control
- France: Association Française pour la Cybernetique Economique et Technique – AFCET
- Germany: VDI/VDE Gesellschaft Mess- und Automatisierungstechnik (GMA)
- Hungary: Scientific Society of Measurement and Automation
- India: Institution of Instrumentation Scientists and Technologists
- Italy: National Research Council
- Japan: The Society of Instrument and Control Engineers
- Korea: Korea Standards Research Institute

- Morocco: Society for Automation and Control
- Netherlands: Royal Institution of Engineers Division for Automatic Control
- New Zealand: The Institute of Measurement and Control (Inc.)
- Norway: Norwegian Society of Automatic Control
- Philippines: Philippine Instrumentation and Control Society
- Poland: Committee for Measurement, Robotics and Automation – NOT
- Romania: Romanian Measurement Society
- Spain: Committee for Metrology, Spanish Association for Quality Control
- Sweden: Instrument Society of Sweden
- Switzerland: Schweizerische Gesellschaft für Automatik
- United Kingdom: The Institute of Measurement and Control
- United States: Instrument Society of America – ISA
- CIS: All-Union Scientific-Technical Society of the Instrument Industry
- Yugoslavia: JUREMA

International Instrument Users Association. The International Instrument Users Association unites three societies, "SIREP-WIB-EXERA" (EXERA=Association des Exploitants d'Equipment de Mesure, de Régulation et d'Automatisme, Association of Users of Equipment for Measurement, Control, and Automation), with the objective of performing suitability tests on measurement and control devices and systems. The concerns in this type testing are operability, safety, availability, accuracy, freedom from interference, ease of maintenance, etc. The results are communicated only to the member firms and the manufacturing firm. Membership is limited to user firms.

Addresses of Organizations Mentioned in Sections 12.2 and 12.3:

Arbeitsgemeinschaft Messwertaufnehmer e.V. (AMA)

12.4. Shows and Fairs

Shows and fairs in the field of process control engineering can be categorized into three major groups:

- Shows devoted to one specialty (e.g., process engineering, manufacturing engineering) and including process control engineering as a sideline. Significant here are ACHEMA for process engineering and the Hannover Messe Industrie for manufacturing engineering.
- Shows oriented toward process control engineering as a whole. In the forefront of this group are INTERKAMA in

Düsseldorf, BIAS in Milan, MESUCORA in Paris, HET INSTRUMENT in Utrecht, ILMAC/INELTEC in Basel, INSTRURAMA in Brussels, C & I in Birmingham, and the ISA Show in the United States.

– Shows that concentrate on a single area of process control engineering, such as Sensor in Nuremberg and Systec, Systems, Laser, and Analytica, all in Munich.

The alphabetical listing that follows is certainly not complete but does give more information on the shows mentioned above, citing the emphasis and a contact address for each.

ACHEMA – International Meeting for Chemical Technology and Biotechnology; includes a congress in the field of chemistry, with special emphasis on process control engineering

Areas of concentration: research and innovation; measurement and control; process control engineering; materials science and materials testing; laboratory and analytical technology; mechanical and thermal processes; packaging and storage technology; safety engineering; occupational safety and health; pumps, compressors, and fittings; biotechnology; environmental protection

Contact address:

DECHEMA
Deutsche Gesellschaft für Chemisches Apparatewesen, Chemische Technik und Biotechnologie
Postfach 15 01 04
60061 Frankfurt/Main
Germany

Analytica – International Technical Show for Biochemical and Instrumental Analytical Technique, with International Meeting

Technical show focusing on analytical laboratory techniques

Areas of concentration: analytical instruments and methods, laboratory technique and apparatus, laboratory data acquisition and processing, industrial chemistry, industrial analytic technique, materials testing, quality control, environmental analysis, biotechnology, medical diagnostics

Contact address:

Münchener Messe- und Ausstellungsgesellschaft mbH
Postfach 12 10 09
80034 München
Germany

BIAS – International Show and Congress in the Field of Automation, Instrumentation, and Microelectronics

Areas of concentration: process computers and process control systems, measuring instruments, controllers, valves, sensors, transducers, transmitters, components and accessories, control devices for processing and fabrication operations, logistics, communications, bus systems, remote control, robotic systems

Contact address:

E.I.O.M.
BIAS Secretariat
Viale Premuda, 2
I-20129 Milano
Italy

CeBIT – World Center for Office, Information, TelecommunicationsInternational technical show for computer techniques

Areas of concentration: screen communications, office communications, text processing, computer technology, data processing, information technology, software, telecommunications, communications technology, communications engineering

Contact address:

Deutsche Messe AG
Messegelände
30521 Hannover
Germany

Control & Instrumentation – National technical show and congress for process control engineering, with emphasis on the chemical industry; held at Birmingham, England

Areas of concentration: process control engineering, computer systems, control technology, actuators, sensors, warning systems, analytical technology, weighing, fiber optics, testing and inspection, CAE/CAD/CAM software, displays and operator interfaces

Contact address:

MGB Exhibitions Ltd.
C & I Secretariat
Marlowe House
109 Station Road
Sidcup, Kent DA 15 7 ET
England

Hannover Messe Industrie – The world's largest industrial show, focusing chiefly on control and process drive engineering but with process control engineering as a secondary theme

Areas of concentration: electrical and electronics engineering; microelectronics; energy, air pollution, and environmental engineering; industrial optics and lasers; materials of construction; surface technology; process drive engineering; control engineering; installation engineering; industrial robots; material-flow engineering

Contact address:

Deutsche Messe AG
Messegelände
30521 Hannover
Germany

Het Instrument – Technical Show for Industrial Instrumentation

Dutch national show in the field of process control engineering; technical show for health care, science, and industry; held in Utrecht

Areas of concentration: devices and systems (sensors, measurement, testing and inspection, weighing, and control engineering); medical technology; laboratory technology (analysis); electronics; research and innovation

Contact address:

Sekretariat Het Instrument
Postfach 1 52
Birkenstraat 108
3760 AD Soest
Netherlands

ILMAC – International chemical show for laboratory technology, chemical engineering, and measurement and automation

Areas of concentration: analytical laboratory techniques; isotope and radiation chemistry; process engineering; measurement, control, and automation engineering; biotechnology; laboratory animal management; environmental protection; health care

Contact address:

Schweizer Mustermesse
ILMAC Secretariat
Messeplatz
CH-4021 Basel
Switzerland

INELTEC – International electrical and electronics engineering show

Areas of concentration: power supply and distribution; energy supply systems; communications; control systems; components; measurement, testing, and inspection; power electronics

Contact address:

Schweizer Mustermesse
INELTEC Secretariat
Messeplatz
CH-4021 Basel
Switzerland

INSTRURAMA – Technical Show for Metrology, Instrumentation, Control, and Automation

National show for the field of process control engineering and laboratory technology

Areas of concentration: apparatus and laboratory equipment; devices, systems, and components for process control and management of industrial automation and informatics in the fields of energy, production, refining, communications, environmental protection

Contact address:

UDIAS
INSTRURAMA Secretariat
Avenue Slegers 203
B-1200 Brussels
Belgium

INTERKAMA – Innovation Market for Measurement and Automation

Largest international show in the field of process control engineering, taking in all aspects of the field but focusing on research institutions, professional qualifications, exhibitor seminars, and congress

Areas of concentration: process control and monitoring systems; measurement and control engineering; sensor technology; analysis and weighing; actuators; communications; data processing; displays and output devices; components and accessories; tools; testing and inspection; services

Contact address:

Düsseldorfer Messegesellschaft
bmH – NOWEA-INTER
KAMA Referat
Postfach 32 02 03
40417 Düsseldorf
Germany

ISA Show – American technical show for process control engineering, with emphasis on a congress; held at various sites

Areas of concentration: measurement and automation technology (see, e.g., INTECH/ISA 91)

Contact address:

Instrument Society of America (ISA)
67 Alexander Drive
P.O. Box 12277
Research Triangle Park NC 27709
United States

LASER – Innovative and Applied Optoelectronics International Technical Show and International Congress

Specialty show with stress on laser technolgy

Areas of concentration: laser and laser systems technology for manufacturing, communications, environment, medicine, science, optronics, components, optical measurement and inspection, holography, pattern recognition, image processing, fiber optics, sensor technology, microwave engineering

Contact address:

Münchener Messe- und
Ausstellungsgesellschaft mbH
Postfach 12 10 09
80034 München
Germany

MESUCORA – International technical show and congress for measurement and control engineering, automation, and industrial data processing, as well as engineering

Areas of concentration: dimensional and mechanical measurements, electrical measurements, process control and automation devices, inspection and test equipment, industrial and scientific data processing, telecommunications systems, engineering, laboratory apparatus, analytical instruments, biological and biomedical metrology, optics and electrooptics, nuclear measurements, vacuum and cryotechnology, instructional and learning aids

Contact address:

Association MESUCORA
11, rue Hamelin
F-75783 Paris Cedex 16
France

SENSOR, Nürnberg – Specialty show focusing on sensor technology

Areas of concentration: sensors, measurement and testing, analytical and weighing technology

Contact address:

Nürnberg Messe GmbH
Messezentrum
90471 Nürnberg
Germany

SYSTEC – International Technical Show and International Congress for Computer Integration in Industry

Technical show focusing on CIM

Areas of concentration: research and experimentation, development, and design of CAD, CAE, and CAM software; consulting; services; system components; networks; workstations

Contact address:

Münchener Messe-
undAusstellungsgesellschaft mbH
Postfach 12 10 09
80043 München
Germany

SYSTEMS – Computers and Communications – International Technical Show and International Congress

Specialty show for computer technology (from PC to the networked data processing scene)

Areas of concentration: hardware, software, communications technology, systems components, user-oriented DP problem solving

Contact address:

Münchener Messe- und
Ausstellungsgesellschaft mbH
Postfach 121009
80043 München
Germany

13. Integration of Knowledge-Based Systems in Process Control Engineering

13.1. Principles

Information technology now permeates the field of process control engineering, not just in the form of computers, storage media, and communications devices, but also via concepts, meth-

ods, and techniques for structuring a wide variety of information. These concepts, methods, and techniques now mark every facet of the field, from the structuring of knowledge about processes to be automated, to the use of increasingly powerful microprocessors in control facilities (sensor/actuator systems, process monitoring and control systems), the structuring of the process control engineer's work during the design, construction, and operation of control facilities, and the availability of computer-aided design tools. Automation is no longer conceivable without them. They are discussed in depth in preceding chapters.

The more advanced technologies of knowledge-based and adaptive systems are already becoming important.

Expert systems, or knowlegde-based systems, arose in the field of AI (artificial intelligence) research, chiefly at American universities and research institutions. The first expert systems appeared in the early 1970s, but their high demand for computer resources prevented their becoming established at that time.

Knowledge-based systems in the sense of a software technology are distinguished by the architectural principle that application-oriented knowledge and processing logic are separate. This can be referred to as a software technology because the field incorporates novel programming methods and techniques. It can also be said that a "paradigm shift" has taken place in informatics, since procedural programming (supported by programming languages such as FORTRAN, PASCAL, and PL/1) has now been joined, on an equal footing, by other paradigms: logic programming (PROLOG = programming in logic), rule programming (OPS 5), functional programming (LISP = list processing), and objectoriented programming (FLAVOR, SMALLTALK, C++, etc.).

Integrated in a hybrid programming system, all these paradigms can be utilized in parallel, depending on what representation or type of knowledge appears most suitable.

The aim of knowledge-based expert systems is to explicitly make available, in a knowledge base, the knowledge of experts as embodied in standards, regulations, and guidelines, but also the knowledge they have gained through experience.

Only later was it recognized that the simple, application-neutral processing logic of "inference machines" (or inference engines) is insufficient for handling certain types of problem.

In addition to the representation of knowledge, an ontological analysis of the problem type is needed. Thus another problem-solving strategy comes into play as used for example for seeking errors in a technical system [834] (diagnostic strategies) or for designing or planning of a technical system. The basis for the latter activity is "planning strategies," which are generally top-down, beginning with functional requirements and proceeding through design alternatives to engineering specifications.

Diagnostic strategies are relatively well understood today, and special expert-systems tools employing them are available. Planning strategies are not so well developed. A point of importance in the problem of planning is "nonmonotonic inference": During planning or design, the planner may find that an approach already adopted is not leading to success, so that design decisions must be withdrawn. Expert systems must be able to keep up with this nonmonotonic decision-making process.

The crucial question in expert systems is still how to acquire experience. In contrast to encoded technical knowledge, which is formalized, standardized, documented, and based on a consensus in the technical world, experience is not formalized, not standardized, not documented, and often not a matter of consensus. Nor can knowledge acquisition be approached by methods of classical systems analysis, since it is concerned with the understanding of mental processes.

For a certain class of problems, adaptive systems or neural networks offer a solution.

Neural networks are now being used successfully for pattern recognition and classification. Pattern recognition refers not just to the typical recognition of images, handwriting, and sounds, but also to the recognition of relationships between physical, chemical, and apparatus-specific quantities.

A neural network is a large, highly connected system of simple processors. Whereas the human brain consists of ca. 10^{12} neurons, artificial neural networks today have few neurons, generally no more than 100.

In such a network, a neuron receives inputs from several others. Only when the sum of the weighted input signals exceeds a threshold value does the neuron transmita signal to the neurons connected to it.

The "programming" of such a network, also called learning, consists of modifying the weights of the connections inside the network such that a pattern presented at the input causes the desired response at the output. One of many programming methods is to modify the internal weights on the basis of the difference between the actual output and the nominal output. When the learning phase is complete, the neural network can interpret new patterns correctly, albeit with a residual error.

New network designer's art consists of finding a design, a learning rule, and suitable representative examples so that an optimal neural network will result at the end of the learning phase.

Another approach to dealing with uncertainty and indistinctness is fuzzy logic. This technique, which has been brought to industrial maturity in Japan, is based on the mathematical theory of fuzzy sets.

In classical logic, a proposition can take only the values "true" or "false," 0 or 1. In fuzzy logic, a proposition or "linguistic variable" is said to have such-and-such percent of value *a* and such-and-such percent of value *b*.

For example, consider pressure as the variable. In an engineering system, a process control engineer might say that the pressure can take on qualitative values such as very low, low, moderte, high, and very high. Now a given pressure – whereby "pressure" is now understood as a linguistic variable in fuzzy logic – can be characterized by the degree to which it belongs to the set of "high" pressures. This is expressed by a numerical value between 0 and 1. Zero means that the pressure does not belong to the set of high pressures at all, while 1 means that it belongs to that set entirely.

A variable might be located, for example, in an intermediate range from high to very high. It no longer takes on a unique value but can be described by, for example, the expression "pressure = (very low = 0.0, low = 0.0, moderate = 0.0, high = 0.3, very high = 0.8)."

Astonishingly, fuzzy logic has found broad applications in control engineering. This should not, however, be surprising, because many quantities cannot be measured exactly and noise of various kinds is often present. A study performed by the Frauenhofer Gesellschaft gives a comprehensive view of the potential applications of fuzzy control, in which an extensive literature collection can be found [847].

Fuzzy-logic control systems in practice often show more stable behavior than conventional methods. Interesting developments have arisen through the combination of classical deterministic control algorithms with fuzzy logic. Combinations with neural networks make is possible to gain the advantages of both approaches. Another technique for finding and retrieving information involves "hypertext/hypermedia" systems. The basis for hypertext is that electronically stored knowledge bases are accessed not with formal query languages or commands but by associative searching in a network consisting of information nodes and arbitrary links between these nodes. Employing the principle of direct manipulation, the user follows a train of associations by clicking the mouse on interesting objects or interesting passages that appear in a document. Nonlinearity is the guiding principle of hypertext. The freedom to navigate within such a network can also lead to disorientation. Tools must therefore aid the user in moving around information space.

The technique of hypertext systems, often combined with object-oriented data bases, is used particularly for technical documentation, standards, and regulations.

Hypermedia systems result when the information nodes are not exclusively text nodes but can also offer graphics, audio, animation, and video sequences.

To summarize, information-oriented process control engineering is already fully operational with no end to its development in sight. This quick review of novel software technologies suggests that the immediate future will see remarkable new advances in information processing. This trend has led to many seminars and tutorials, with special mention being made here of the tutorials at the GMA Congress 1993, in which fuzzy control, neural nets modelling dynamic systems, ER/SADT, and information-oriented modelling concepts were reported in detail.

13.2. Knowledge-Based Approach

Introduction. The ideal structure of a process control system is presented in Chapter 7. In Figure 254, the "remote" components include an AI (artificial intelligence) computer, which forms the hardware basis for knowledge-based systems. In process control engineering, the latter term is understood as referring to a combination of conventional process automation approaches and AI methods.

The need for knowledge-based systems using AI computers in process control engineering arises from the development of the object being automated, that is, the processing system.

For example, the continuing trend toward more intensive process control – a consequence of technological progress in process, manufacturing, and automation engineering – has led to a number of qualitatively new and distinct features in modern production facilities. These include large product throughputs, extreme process parameters, operation up to the stability limits, high parametric sensitivity, direct coupling of some process units without intermediate storage, and a high degree of material, energetic, and informational interconnection between production areas and operational divisions. The objectives of process control have come to include process securing (enhancement of process reliability), plant availability, process efficiency, product quality, production flexibility, and environmental safety. For these reasons, complex control tasks at higher levels are steadily gaining in importance for process automation. Most of these tasks involve the solution of the following problems [848]:

- The complexity and high dimensionality of control tasks (more than five control variables that can be freely selected)
- The incomplete observability and the nonlinearity of the subsystems
- Compliance with complicated side conditions (including a number of logical conditions)

The classical methods of modeling and control often fail on grounds of expense or because of parameter identification problems or real-time requirements. Generally, higher-level control tasks can be accomplished only when their complexity and dimensionality are reduced by situation recognition techniques and when experiential knowledge (to delimit the solution domain) is combined with situational models (to define the solution point).

In the context of knowledge-based systems for process control engineering, the principal AI elements are expert systems, artificial neural networks, and fuzzy systems. Expert systems and fuzzy systems (both employing methods of mathematical logic) are similar in their information structure. They are used as rule-based systems in process automation, in both open loops (consultative systems) and in closed control loops. The sole difference is that expert systems employ "distinct" knowledge (precisely measured process signals, unambiguous and either/or rules) while fuzzy systems employ "indistinct" knowledge (membership functions, fuzzy rules). From the applications standpoint, artificial neural networks are very similar to statistical methods of process modeling.

This section deals mainly with the use of expert systems and neural networks. AI methods are just beginning to find wide use in process control engineering [848].

Rule-Based Systems. The main types of rule-based systems used in process control engineering are expert systems and fuzzy systems. These seek to imitate the process of human thought on a phenomenological level.

If these systems are to be used as control elements in process control engineering, it is necessary to analyze the process employed by the operator of a production plant in solving problems. Figure 430 shows the subtasks and the solution process for the example of a reaction to disturbances in the process plant.

An analysis of this problem-solving process shows the following:

- The solution process involves the steps of diagnosis, optimization, and planning. Each step is separated from the next by a simulation phase. In this way, solutions are validated on simulation models, which may be both heuristic models and, often, mathematical models "in the operator's head" (thought models). These simulation techniques, whether practiced consciously or not, form part of a continuous iterative mental process, which ultimately leads to optimal

Figure 430. Tasks in knowledge-supported process control

conduct of the process. In other words, the suitability or optimality of the target situation is investigated by simulation and then corrected, leading to a corrected target situation, which in turn is simulated, and so on until the best result has been attained according to the operator's judgment.

– A nominal/actual comparison, the construction of control algorithms, and the determination of setpoint values, all as components of the diagnosis, simulation, and planning steps, can be performed with conventional control resources. The result is a higher degree of

automation and hence the accomplishment of process stabilization tasks.
- Conflict-resolution strategies in the context of optimization tasks can generally be implemented only by using artificial intelligence methods, namely the accomplishment of tasks relating to process optimization and securing. As a rule, knowledge-based systems here operate in consultative mode, with no increase in the degree of automation. If these tasks in all of the solution space are algebraically describable, however, it is possible to dispense with AI components.
- Knowledge-based systems cannot handle background knowledge (e.g., historical knowledge about the design process, knowledge of maintenance strategies or of the market situation). This part of the problem-solving process thus cannot be supported by knowledge-based process control engineering.

There are no fixed procedures for modeling the problem-solving process as a mental process. This is the fundamental distinction to the mathematical modeling of engineering processes, in which the application of balance equations (mass, enthalpy, and momentum balance) leads to an unambiguous and exact mathematical model.

Analyzing the problem-solving process from the standpoint of process control theory allows two classes of tasks to be identified: disturbance analysis and control synthesis.

Disturbance analysis encompasses solving the following tasks:

- Determination of primary casues of disturbances: Disturbances arise through slow parameter drift due to wear, contamination, and corrosion, or through sudden structural changes due to the failure of subsystems.
- Determination of secondary consequences of disturbances: Frequently occurring secondary effects are bottlenecks in feedstocks, energy-transfer media, intermediate products, or recirculating streams in adjacent process sections or in downstream process steps, which (depending on the process dynamics) most often manifest themselves immediately but, ultimately, further increase the resulting production losses.

On the basis of the primary causes of disturbances, a simulation of the dynamic consequences of disturbances thus provides important supplemental information about the objectives of measures taken against disturbances.

The following tasks must be carried out in control synthesis:

- Identification of primary repair measures means deriving the repair measures by which the primary causes of disturbances can be directly remedied.
- Determination of current system reserves: Along with the medium-term removal of primary causes of disturbances, in the short term it is necessary to make a control decision that will bridge over the failure of the malfunctioning subsystems for the duration of the repair measures and thus minimize the resulting production losses.
- Generation of a provisional operating regime: On the basis of the current system reserves, a new process regime is generated that will bridge over the system failure for the time required to remedy it and thus minimize the resulting production losses.
- Restoration of operation: Once the primary causes of disturbances have been remedied, the system must be restored to its normal state. This also requires for coordination of all subsystems.
- Process optimization: Current system reserves, as well as feedstock and energy resources, are deployed such that a technical-economic criterion takes on an optimum value while compliance with technical and economic constraints is maintained.

In what follows, some theoretical principles of rule-based systems are presented. These are essentially based on mathematical logic.

Neural Networks. In contrast to expert systems, artificial neural networks imitate the process of human thought at a biological level [848, 849]. The aim is a functional simulation of the human brain or of the human nervous system, which comprises some 25 billion nerve cells (neurons). Figure 431 shows a single neuron and the way in which neurons are interconnected.

A neuron receives its input information via the dendrites, which are connected by synapses

Figure 431. A biological neuron

Figure 432. Functional diagram of an artificial neuron

to the information outputs of other neurons. Each neuron has only a single information output, the axon, which may be connected to as many as 10^4 "downstream" neurons through dendrites. From the sum of the inputs, an output dependent on the state of the neuron is generated and passed on to the downstream neurons by way of the axon. Biological information is thus transported throughout the network (nervous system), whereby it may also be modified. A significant feature of the process is the massive parallelism of information transport and processing. The above properties of neurons allow an abstract model of an artificial neuron (processing element) to be devised, which is described by the following rules (see Fig. 432):

- A neuron can adopt either of two states, the resting state and the action state
- A neuron j in layer s has multiple inputs $x_{ji}^{s-1}, \ldots, x_{jn}^{s-1}$ (synaptic connections) and one output (axon) x_j^s
- The output of the neuron is connected to the inputs of other neurons, and in this way a neural network is formed
- Some inputs and outputs of the neurons are connected to the outside world
- A neuron enters the action (excited) state when a sufficient number of its inputs have been excited

In this discussion,

x_{js}^{s} denotes the instantaneous output states of the j-th neuron of layer s,
w_{ji}^{s} the weightings of the connections of the i-th neuron in layer $s-1$ to the j-th neuron in layer s, and
I_j^s the weighted sum of the inputs of the j-th neuron in layer s.

The last rule, in particular, implies that the state of an artificial neural network depends only on the state of its elements. The individual neurons thus operate independently of one another.

For process control engineering the features of interest are the basic functions of neural networks (pattern association, pattern reconstruction). Here "patterns" are vectors (e.g., sets of measurements used to characterize a plant state or to assess product quality).

Three types of processing elements (units) are distinguished in an artificial neural network:

- Input units, which acquire their input information from the surroundings of the network (e.g., sensors) and are "visible" from outside the system
- Hidden units, which process incoming information and are "invisible" from outside the system
- Output units, which deliver output information to the surroundings of the network (e.g., actuators)

The individual units are grouped by function into layers, which are interconnected in a manner that depends on the problem. Figure 433 shows a typical multilayer network. Such networks are used principally for classification tasks.

Note that the behavior of the artificial neural network is strongly influenced by the network structure along with other factors.

A distinction is often made between the normal working phase (recall phase) and the learning or training phase of a neural network. Before the network becomes able to carry out given tasks, it must be trained for those tasks. Learning may be supervised or unsupervised. The first

Figure 433. Multilayer network with one hidden layer

mode involves learning on the basis of specified examples. The back-propagation method is well known. In unsupervised learning, the network independently trains itself on the basis of rules in the input data (e.g., patterns).

In back-propagation, the output of the j-th element of layers s is determined by transformation with transfer function $f\left(I_j^s\right)$ (see Fig. 434 for an example).

$$x_j^s = f\left[\sum_{i=0}^{n}\left(w_{ji}^s \cdot x_i^{s-1}\right)\right] = f\left(I_j^s\right) \tag{13.2.1}$$

In back-propagation networks, the quality of the neural network is usually evaluated by a global error function E, which is needed in order to define local errors in the output layer and thus initiate the back-propagation of errors.

If it is assumed that vectors $\boldsymbol{i}$ and $\boldsymbol{d}$ are given to the network as the input and output patterns during the learning phase, while $\boldsymbol{o}$ represents the output vector calculated with the instantaneous weights, a global error function for the artificial neural network referred to the expected output $\boldsymbol{d}$ can be defined as

$$E = \frac{1}{2}\sum_{i=1}^{m}\left(\boldsymbol{d}_i - \boldsymbol{o}_i\right)^2 \tag{13.2.2}$$

where m is the number of components of vectors $\boldsymbol{d}$ and $\boldsymbol{o}$.

The aim of the learning process is to minimize the global error E of the network by selecting weights w_{ji}^s. Given the current set of weights

Figure 434. Possible transfer functions of a processing unit in a neural network

w_{ji}^s, the problem is to determine whether and by how much these weights must be changed. The formula

$$\Delta w_{ji}^s = -\alpha \cdot \frac{\delta E}{\delta w_{ji}^s} \tag{13.2.3}$$

is used for this purpose, where α is the learning coefficient.

Each weight is thus corrected in accordance with the magnitude and direction of the negative gradient on the surface of E. The partial derivative in Equation (13.2.3) is calculated as

$$\frac{\delta E}{\delta w_{ij}^s} = \frac{\delta E}{\delta I_j^s} \cdot \frac{\delta I^s}{\delta w_{ij}^s} \tag{13.2.4}$$

Setting

$$e_j^s = -\frac{\delta E}{\delta I_j^s} \tag{13.2.5}$$

and applying the chain rule twice gives the following relation between e^s and e^{s+1}, needed for the iterative computation:

$$e_j^s = f\left(I_j^s\right) \cdot \sum_{k=1}^{m}\left(e_k^{s+1} \cdot w_{kj}^{s+1}\right) \tag{13.2.6}$$

where m is the number of processing elements in layer $s+1$.

For the output layer

$$\begin{aligned} e_k^o &= -\frac{\delta E}{\delta I_k^o} = -\frac{\delta E}{\delta o_k} \cdot \frac{\delta o^k}{\delta I_k^o} \\ &= \left(d_k - o_k\right) \cdot f\left(I_k^o\right) \end{aligned} \tag{13.2.7}$$

Combining equations (13.2.3) and (13.2.4) and using Figure 432 gives

$$\Delta w_{ji}^s = x \cdot e_j^s \cdot x_i^{s-1} \tag{13.2.8}$$

Equation (13.2.8) represents the delta learning algorithm of the back-propagation method. Now the mechanism of back-propagation in the artificial neural network can be made explicit:

- Forward propagation of the inputs up to the output layer with the aid of Equation (13.2.1) and determination of the error at the output layer
- Successive correction of the weightings w_{ji} (with Eq. 13.2.8) during the process of back-propagation toward the input layer
- Recalculation of the output layer error with Equation (13.2.1) and recorrection of the w_{ji} with Equation (13.2.8), and so forth

Algorithmic Integration of Knowledge-Based Systems. Expert systems and neural networks have both advantages and disadvantages for process control (see Table 15).

Table 15. Comparison of expert systems and neural networks

System	Advantages	Disadvantages
Expert systems, fuzzy systems	use of surface knowledge	difficulties in knowledge acquisition (e.g., rules, membership functions)
Neural networks	ability to learn	difficulties in interpretation of solution (e.g., no possibility of explanation)

Figure 435. Algorithmic integration of knowledge-based systems

A useful way of compensating for the drawbacks is to employ both kinds of systems together. Figure 435 illustrates this point; the formulas presented there are explained in the text. This also enhances the software reliability. The artificial intelligence components determine the solution domain, while the conventional algebraic methods of process control give the solution point. From the standpoint of automation theory, the result is thus a localization of the process control task.

The mathematical models are significantly simplified in this way, because a mathematical description is needed only in the vicinity of the solution point. Linear models may well be adequate. Thus the control algorithms relating to process optimization, stabilization, and securing must be run under real-time-capable software, either on the process monitoring and control computer or on a special AI computer.

The definition of the solution domain by expert systems and neural networks (essentially in the context of classification tasks) is treated above. Now let us examine in more detail the application of algebraic methods to the determination of the solution point. It is assumed that a processing system can be broken down into subsystems (SS_n), interconnected by material and energy streams (see Figs. 436 and 437). This means simply that the phase model of production is employed in developing the software structure (see Chap. 2).

The following aspects are crucial in analyzing the system into subsystems:

- Topological (breakdown into technological elements, apparatus groups, etc.)
- Dynamic (breakdown into subsystems by dynamic properties, e.g., duration of dynamic transient processes, time lag)
- Combination of topological and dynamic aspects

The following notation is used:

$$\boldsymbol{X}_n = (U_n, Z_n, Y_n)$$

represents the vector of the process parameters of the n-th subsystem;

$$\dot{\boldsymbol{x}} = (X_1, X_2, ..., X_N)$$

the vector of the process parameters of the entire system;

$$\boldsymbol{X}_n = f_n(X_n)$$

the simplified mathematical model of the n-th subsystem;

$$G(\boldsymbol{X}) = 0$$

the coupling conditions of the subsystems; and

$$Q(\boldsymbol{X})$$

the goal function in process optimization, the Lyapunov function in process stabilization, and the negative first derivative of the Lyapunov function with respect to time in process reliability enhancement and quality assurance.

Thus the algorithmic structure of all process-control tasks is unified. As a consequence, marked simplifications have been achieved in the applications software (fewer software errors, better software maintenance).

Figure 436. Decomposition of a technological system

Figure 437. Example of a coupled total system

The use of the optimization condition $Q(\mathbf{X}) \rightarrow \min$ naturally requires some explanation.

With regard to the algorithmic integration of knowledge-based systems, conventional mathematical models are used as simulation systems for generating examples (in the case of neural networks) and of unmeasurable process information (in the case of expert systems). This point will be treated in more depth below.

Technical Integration of Knowledge-Based Systems. *General Principles of Integration.* Figure 438 shows the technical integration of expert systems and neural networks into the process monitoring and control plane. Knowledge-based process control can be represented in three levels:

- Elementary situation recognition with conventional methods of limit monitoring, deterministic or statistical class ordering, and trend analysis.
- Expert systems and neural networks combined with simulation systems based on mathematical models of the technological process. The objective is to identify the domain of the desired solution to the control problem.
- Conventional process control with the use of local or simplified mathematical models.

Integration of Expert Systems. The recommended procedure for technical integration of expert systems is to implement a real-time-capable expert system shell (expert system with empty knowledge base, i.e., without rule knowledge) on the control or AI computer, then fill it with concrete process-control knowledge in the course of knowledge acquisition (see Section 13.3). Such expert system shells must imitate the problem-solving process described here. A successful example is the PROCON expert system shell, which has been implemented in several cases [850–853]. This shell will be described in more detail in what follows.

System components: PROCON is subdivided into a development system and a runtime system with the following components (Fig. 439):

- Knowledge representation: object-oriented representation concept for explicit structuring of problem spaces

Figure 438. Technical integration of knowledge-based systems

Figure 439. PROCON system components

- Knowledge manipulation: cooperative problem-solving processes for diagnosis and application of expert knowledge toward efficient delimitation of a solution
- Knowledge acquisition: problem-specific development environment for input, inspection, and transformation of knowledge into a runtime-efficient representation
- Knowledge consultation: user environment for verification and consultation of implemented knowledge bases

PROCON incorporates process, program, and dialog interfaces with the following features:

- Preparation of all needed process variables that can be acquired on-line, through coupling with the process control system
- Preparation of all needed process variables that can be acquired off-line, through interactive dialog with operating personnel
- Automatic interrogation of redundant information sources by the expert system whenever failures of measurement stations are reported
- Manual configuration of charge-dependent process parameters with parameter sets or in interactive dialog with operating personnel
- Rule-governed activation of external simulation and optimization programs via the program interface
- Manual, timed cyclical, or external consultation start

Requirements on the Knowledge Base. Applying expert systems to process control tasks means keeping pace with the process dynamics so that the integration of the knowledge base can be insured and critical reaction times met. Heavy modularization of expert knowledge into small knowledge units is dictated by both the need for adequate runtime efficiency of knowledge processing and the need for easy maintainability of the knowledge base as technological conditions change and operational experience is gathered. One useful modularization principle results from a division into disturbance and control classes. The set of all disturbances can be imaged on a set of disturbance classes that are qualitatively distinguished by primary causes and secondary consequences of disturbances. Similarly, all control actions can be placed in control classes on the basis of the disturbance class to be compensated and the available system reserves. If the two classifications are successively refined, a tree-like structure of disturbance and control classes is created. In the terminology of expert systems technology, this is referred to as a class hierarchy (taxonomy) of prototypical problem classes (objects). Descending through the problem hierarchy thus corresponds to localizing the current system disturbance and the resulting therapeutic control action. On a path from the root to a leaf of the taxonomy, each object encountered makes a contribution to the total solution of a problem. Each object contains a partial knowledge base made up of declarative (facts), functional (functions), and procedural (rules) knowledge specifications (Fig. 440).

Each object has access to the knowledge of all its predecessors in the problem hierarchy (inheritance):

- Declarative knowledge includes process information that can be automatically updated (values that can be acquired by on-line measurement, values that can be acquired by off-line laboratory work,etc.);user-configurable (technological) constants; interference variables derivable in the course of problem-solving; and representations parametrizable and external programs invokable by the rules of expert knowledge application (simulation and optimization models).
- Procedural knowledge. The following rule bases can be defined in each object:
- Rules for application of expert knowledge ("expertise" rules) are forward-chained production rules for the derivation of interferences from a given problem class (Fig. 440). They can derive interference variables, form solution texts to be displayed, parametrize representations for output, and invoke external programs for simulation and optimization.
- Diagnostic rules are classification rules for the derivation of so-called sympathy ratings for the objects in a problem hierarchy (Fig. 441). The expert system uses these ratings to decide what route to follow through the problem hierarchy, that is, what problem classes actually need to be examined in a concrete disturbance situation.

Problem Solving. The object-oriented structuring of the problem space permits efficient

Figure 440. Concept of knowledge representation in PROCON

problem reduction through two problem-solving levels:

- Higher problem-solving level: Starting from the root of the problem hierarchy, a heuristic graph searching procedure determines a route through the structure of the problem space. In so doing, it establishes which problem classes actually need to be examined in a concrete disturbance situation, and in what order. The examination of a problem class is initiated by an activation message to its local problem-solving process.
- Lower problem-solving level: The local problem-solving of an activated object begins with a process coupling, then continues with an expertise and diagnostic process. Through the process coupling, all process features defined in the given object (with respective coupling parameters) are first updated. The expertise process (application of expert knowledge) that follows next evaluates the expertise rule base of the object in order to derive interferences from the problem class. Finally, the diagnostic process uses the diagnostic rule base of the object to rate its successors in the problem hierarchy.
  The remainder of the problem-solving process follows the rules of mathematical logic as described above.

Development Environment. The work of developing practically relevant knowledge bases is commonly divided among specialist experts (process engineers, automation engineers, expert operators) and, in the long term, makes possible the maintenance of the knowledge base as technological conditions change and operational experience is gathered. For this reason, special value attaches to interactive tools for the support of incremental, problem-specific knowledge acquisition. In PROCON, the acquisition component integrates the following aids in a self-contained development environment:

- Knowledge input: Graphically supported structure editor for taxonomy input. Mask editors for fact input, screen editors for rule and function definition.
- Knowledge inspection: Automatic search for inheritable knowledge specifications anywhere in the knowledge base; compressed explanation of defined knowledge contents of the active inheritance hierarchy during knowledge input.
- Knowledge transformation: Transformation of a problem-specific external knowledge representation into a runtime-efficient internal representation; formal-language or natural-language rule notation can be selected.
- Knowledge verification: Testing for syntactic closure and semantic consistency in the active inheritance hierarchy during rule translation; testing for adequacy and completeness in a comprehensive trace environment with case data management.

This development environment is the basis for knowledge acquisition as described in Section 13.3.

Integration of Neural Networks [854]. In comparison with the conventional methods of process control engineering, neural information processing requires high-performance storage media as well as fast processing units (and possibly the use of special processors). Furthermore, the practical deployment of neural networks calls for ingenuity in network configuration as well as a training technique optimally suited to the application.

Hardware and Software Implementations. The recommended hardware support for neural network algorithms differs from the classical Von Neumann structure. The following solution approaches are of interest:

- The use of special neural processors to speed up serial operation. These units feature a separate floating-point processor, a supplemental cache memory, and complete primary storage capacity and employ the pipelining principle. Examples are the PC boards made by SAIC Corp.
- Multiple-instruction, multiple-data structures, which can be implemented with available "transputer" components; a number of software packages are already on the market for transputer boards.
- The use of vector processors. If these devices have a sufficient number of processor components, they make it possible to determine network activity layer by layer (i.e., to determine the activation vectors section by section with a high degree of concurrency).

At present, software simulators are used to convert the various network types to the computing and monitoring/control hardware currently used in process automation. Their implementation on general-purpose processors (e.g., Intel 8086) meets the requirements of flexibility, portability, and high integrability.

Only in exceptional cases can a dedicated implementation be recommended, especially since there are a number of powerful neural shells on the market. These systems generally have communications interfaces to the user and file levels and offer a wide range of distinct network types. Particularly important for integration into process control systems are runtime routines that enable customized, memory-efficient source code runtime modules to be integrated into the applications software. One example of such a software simulator is a development system called Neural Works Profes-

sional II, published by Neural Ware Inc. and intended for PC and workstation environments.

Note, however, that straight software implementations have the drawback of limited capacity, both in the training and in the implementation phase. A combination of dedicated hardware and dedicated software should therefore be preferred. The integration of parallel processing structures (e.g., in the form of transputers) into monitoring and control systems is anticipated.

13.3. Knowledge Engineering

Procedures and Methods. The creation of the knowledge base is the key step in the integration of knowledge-based systems into process control engineering. This procedure employs methods of knowledge engineering.

The term knowledge engineering denotes the totality of the processes involved in the design, implementation, and maintenance of expert systems (when expert system shells are used, this essentially means filling a knowledge base). Knowledge engineering thus continues throughout the life cycle of an expert system. The analogy to software engineering is clear. Knowledge engineering is the bottleneck in expert systems development (the same applies to automation engineering). Thus there is a parallel to the "software crisis" in the realm of conventional software.

Knowledge engineering, which can also be termed systems analysis, involves close collaboration among process control engineers, process engineers, and information specialists (Fig. 442).

Figure 442. Interdisciplinary cooperation in knowledge engineering

In empirical social research, many years' experience and a broad methodological potential are available for the acquisition of knowledge and the traditional, nonformalized use of expert knowledge. Because these are also available to knowledge engineering, it is not surprising that the techniques currently in use for the acquisition of expert knowledge are largely derived from the methodological inventory of empirical social research. The techniques must, however, be modified to suit the needs of this special application area of process control engineering. Desirable, above all, is an appropriate combination of these techniques with the methodological potential built up over decades in theoretical and experimental process analysis. The knowledge to be incorporated in expert systems is generally found in the most diverse knowledge sources: technical manuals, operating instructions, case studies, and reports, but also data files and databases that may contain operational data for concrete process situations. In addition, personal experience and the knowledge of technical specialists (experts) is also sought. It is the last of these knowledge sources that is crucial in process automation. Moreover, a theoretical process analysis may also involve the creation of mathematical models that are then available as secondary knowledge sources.

Accordingly, a complex utilization of all knowledge sources – theoretical mathematical models, process data, and operator experience – is to be recommended as a way of reducing effort (see Fig. 443).

Figure 443. Reduction of effort by complex utilization of all knowledge sources

Formulated in general terms, the knowledge acquisition component of an expert system must support the transformation of this very heterogeneous knowledge to a homogeneous form, so

that it corresponds to the representation scheme defined by the structure of the knowledge base and by the interference component. Thus the knowledge acquisition component aids in the description of information or knowledge from the area of the user's tasks, building up a knowledge base from this information. The wide variety of knowledge sources makes this an exceedingly complicated problem, which entails a considerable effort in the case of an expert system for process automation. In present-day expert systems, various "manual" techniques are often employed for knowledge extraction; editors support only the final input to the knowledge base. When knowledge is prepared manually, however, relevant information is frequently lost or is not acquired at all. It is thus all the more important to develop knowledge acquisition components that will interactively support and assist the knowledge engineer (who is, as a rule, the process control engineer) in performing this task.

On the basis of these general aspects, a four-phase concept of knowledge engineering is recommended. This concept is oriented primarily toward process automation [855, 856]. The fundamental idea is to subdivide the iterative process of developing an expert system into the following phases (see Fig. 444):

- Definition
- Acquisition
- Operationalization
- Maintenance

Figure 444. Four-phase concept

The definition phase provides a first global survey of the application domain. A specification of requirements must be created; that is, the problems for solution must be stated, their transformation into objectives and tasks of the expert system must be defined, and the feasibility of the expert system project must be investigated. In other words, the control task is established in this phase. The definition of the control task may be supported, for example, by comparing the disturbance amplitude D_z and frequency f_z for each control object. An analysis of this kind is done for the dominant disturbance in each control problem. Figure 445 shows that closed regions can be defined in the $D_z - f_z$ plane, in which process securing, optimization, and stabilization are to be performed.

Figure 445. Relationship between automation tasks and properties of the disturbances

These process control components are defined as follows (see also Section 4.2):

- Process stabilization: Compensation of correctable disturbances with the aim of holding the process parameters constant at specified values
- Process optimization: Determination and setting of control variables so as to optimize a specified criterion while complying with specified restrictions
- Process securing: Compensation of uncorrectable disturbances with the aim of preventing unacceptable process states and product qualities or of minimizing their consequences

Figure 445 also shows, as a function of f_z, the trend in the use of expert systems and mathematical algorithms (conventional process control) as well as the use of consultative systems (open loop) and automatic systems (closed loop). In

this way, it is possible to identify a certain number of standard situations to which a particular control task applies. Expert systems are especially well-suited to the solution of process securing tasks, since as a rule there are no mathematical models for large disturbance amplitudes (emergencies), although a certain amount of empirical knowledge exists. The requirements worked out in the definition phase must be set forth in an appropriate form (specifications).

The acquisition phase includes analysis of disturbances, causal relationships, and possible control responses, as well as the aggregation of results into situation and control classes. The process analysis yields a formal model of the problem space in which the general questions to be answered in the definition phase should be detailed. The real difficulties in this phase lie in the design of knowledge bases. The knowledge should be structured to match the technology. It must directly mirror the operator's experience or mode of action and be determined chiefly by automation theory. In the operation phase, the knowledge is structured to match the system, as specified by the representation mechanisms that the expert system shell provides. This transformation of knowledge requires a knowledge engineer with experience and knowledge in many scientific disciplines.

Now let us take a closer look at "technology-like" structuring. The structure of the knowledge in this case is derived from the structure of the control object; a different form of structuring is generally meaningful in each disturbance class. Experience has shown that the technological system can be broken down into subsystems, each of which is controlled in autonomous fashion while all the subsystems are simultaneously coordinated. The decomposition of the entire technological system is based on the phase model of production (see Chap. 2). This principle can be illustrated for the example of process securing. The system is decomposed into a certain number of subsystems or levels, depending on the disturbance class; these subsystems show relevant differences in the dynamic properties relative to the dominant disturbances (Fig. 436). The upper (i-th) plane reacts with virtually no time lag to signals from the lower ($i+1$-th) plane. Each level contains a number of subsystems, which are connected to one another by energy, material, and information streams and exhibit similar dynamic properties.

On the basis of the structure of the control object, it is recommended that a hierarchical structure with multiple coordination levels be used for the process securing system. The subsystems should have the greatest possible autonomy (see Fig. 446). The subtasks of knowledge-based process control that are solved are the ones described above under "knowledge-based systems": determination of causes and consequences of disturbances, identification of control actions for the subsystems and for the system as a whole. One of the fundamental ideas in the technology-oriented structuring of knowledge is this: When an uncorrectable disturbance z_i takes place, the application of algorithm A_{1i} detects and compensates this disturbance (determination of primary causes of disturbance, derivation of primary repair measures). The "compensation" of a disturbance z_i means controlling a subsystem such that the given system is in a failure state for a time Δt shorter than some acceptable value Δt_{acc} ($\Delta t < \Delta t_{\mathrm{acc}}$). If this fails, coordination of two adjacent subsystems S_i and S_{i-1} is effected by using $A_{2(i-1)}$. First, the effect of the disturbed or failed subsystem S_i on S_{i-1} is identified (determination of secondary consequences of disturbance); second, the instantaneous dynamic reserves of S_{i-1} for compensating the failure of S_i are determined; third, a provisional regime (e.g., part-load or turndown regime) is generated. If even these steps do not compensate the disturbance, three subsystems are coordinated (for example, S_i, S_{i+1}, and S_{i+2} by using A_{3i}), then four subsystems, and so forth. This process is continued until the disturbance z_i has been compensated. Whenever a new subsystem is included, the above steps are repeated: identification of secondary consequences of disturbance, determination of instantaneous system reserves, and generation of a provisional regime. If successful compensation of the dangerous disturbance has not been achieved despite coordination of all subsystems, an emergency shutdown of the technological system is performed. In the context of knowledge-based process control, these coordinated shutdown modes can also be treated as provisional regimes. The normal regime is restored when the disturbance z_i is no longer present.

The operationalization phase includes the "system-like" structuring of the knowledge as well as steps to make the expert system functional.

Newly acquired knowledge is added during the maintenance phase (e.g., in the form of new "rules"). In addition, portions of the knowledge basis may have to be replaced altogether if changes take place in the technology. Expert systems are considerably more maintainable than conventional software systems, which is largely due to the fact that software errors do not necessitate complete reprogramming (software technology aspect). This leads to enhanced reliability of the process control system and lower maintenance costs.

Figure 446. Structuring of a process securing system

Application Example. A chemical plant for the production of poly(ethylene terephthalate) fibers (trade name Grisuten) is equipped with a TDC 3000 process control system. The main tasks of the plant operator fall into the following categories:

- Process monitoring, the principal tasks being the detection and diagnosis of disturbances
- Process securing, i.e., the prevention of situations that would endanger the plant

In case of a disturbance, the operator must identify and implement a suitable reaction on the basis of available process information. Frequent operator interventions are needed in the following situations:

- Startup and shutdown
- Modifications of the operating regime
- Failure of plant sections
- Occurrence of critical process states that impair more than one plant section

Localized disturbances can generally be compensated by the existing automation system. In the above situations, the quality of operator decisions varies widely. Along with qualitatively good decisions by some operators, wrong decisions – some of them serious – are made by other, less experienced operators, especially when they are under psychological stress. Furthermore, the required specialist knowledge is commonly split up among several operators. The basis for an operator's decisions is essentially his own experience; theoretical background is less important. The main feedstocks are ethylene glycol and terephthalic acid (TPA). The process is continuous and can be broken down into the following phases (see also Fig. 447).

Metering/homogenizing. The feed materials are metered in fixed proportions into the paste mixer, where they are homogenized. Metering errors or inadequate homogenization of the feeds can lead to serious disturbances in the downstream system and to a major degradation of fiber quality.

Esterification. The reaction mixture is converted to diglycol terephthalate in a two-stage esterification reaction. The reaction is strongly endothermic, so heat has to be supplied. This process is carried out under vacuum, and the extracted vapors are distilled to recover ethylene glycol, which is recycled to the metering/homogenization stage. The crucial point here is to insure a minimum residence time of the reaction mixture in the reactors, to attain an appropriate degree of esterification.

Condensation. The diglycol terephthalate from the esterification stage is polycondensed to poly(ethylene terephthalate) in four condensation stages. The strongly endothermic reaction is carried out under vacuum with heating. The important quality criterion is that an appropriate degree of polycondensation must be attained after final condensation.

Spinning/finishing/extrusion. The polymer melt is spun and/or extruded in a melt-spinning stage. A number of treatments are performed on the spun filaments, after which they are ready for shipment. Every process step in the condensation and spinning/finishing/extrusion stages results in a significant increase in the viscosity of the reaction mixture.

The task of the expert system is to serve as a decision aid to the operator in carrying out

Figure 447. Process flowsheet
VE = esterification; VK = precondensation; RSR = ring-and-disk reactor; EG = ethylene glycol; TPA = terephthalic acid; HTF = heat-transfer fluid

process monitoring and securing tasks at the higher level. In particular, these tasks include:

Startup:
Cold startup of the chemical section of the plant (mean product temperature $< T_{\min}$)
Warm startup of the chemical section of the plant (mean product temperature $> T_{\min}$)
Failure of plant sections:
Failure of heating system for heat-transfer fluid (HTF)
Occurrence of critical process states:
Vacuum disturbance
Viscosity disturbance
Disturbance of mole ratio/COOH groups
Level and flow rate disturbances

Figure 448. Disturbance classes and their interrelationships

The aim in reacting to disturbances is to insure high process reliability and product quality with the minimum reduction in plant capacity. Whenever possible, process data should be acquired from the process on-line, without placing extra demands on the operator. Interviews with experts have shown that all disturbance classes are interrelated in a complex manner (see Fig. 448). For this reason, in particular, they have not yet been completely brought under control.

Now let us examine the practical creation of a knowledge base more closely. The four-phase concept described above is applied to the disturbance class "HTF heater failure." The heat-transfer-fluid heating unit supplies heat to the strongly endothermic reactions in the VE and VK/RSR reactor groups (Fig. 447). A failure or loss of capacity in the HTF heater always results in severe disturbances (Fig. 448):

- Level and flow rate disturbances: Because of the rapidly cooling product lines, continuous flow of product between the individual reactors is not insured after just a short time. The consequences are unstable levels and residence-time disturbances.
- Vacuum disturbances: Unstable filling levels result in foaming in the reactors, which can result in product being carried into the vacuum system.
- Mole ratio disturbances: Residence time disturbances lead to an excessively high or low conversion of the reaction medium. The consequence is a severe decrease in fiber quality

and possible disturbances to the viscosity or COOH groups of the product.
- Viscosity disturbances: If the viscosity of the reaction process departs from the acceptable tolerance range. Both the processability and the quality of the product fall off drastically.
- COOH group disturbances: Because of excessive residence times, much of the feed ethylene glycol flashes off, leaving an excess of TPA and thus of COOH groups. As a result, major decreases in fiber quality occur.

For each of these disturbance classes, the proper responses to offset the disturbance (process securing) were ascertained by interviews with experts. The typical procedure for process securing (see above) was used as the basis for these interviews. Starting from the dynamic properties relevant in the case of an HTF heater failure, the technological system was broken down into subsystems S_1 (HTF heater) and S_2 (homogenizing, esterification, condensation, RSR reactor). The process securing system, in analogy to Figure 446, has the structure shown in Figure 449. This structure also describes the procedure used by the plant operator to compensate for the disturbance. The operator moves down a tree structure, level by level, until a solution to the process securing problem has been found.

Figure 449. Structure of the process securing system upon a failure of the HTF heater

Figure 450 shows this procedure schematically. The respective decisions and actions are listed in accordance with the algorithms A_{ij} in Figure 438.

Figure 450 also demonstrates the structure of the technology-oriented knowledge base; reactions to possible downstream disturbances (level, vacuum, etc.) are merely indicated. Direct conversion to the expert system would have the consequence that many rules or knowledge items would have to be input more than once (e.g., 12 times for the cold and warm startup knowledge sub-base). This expresses the fact that several disturbance classes can be correlated with a control class. Large memory problems would result. Furthermore, searching problem space with such a tree would narrow down the problem very slowly, so that the solution process would not be efficient enough (real-time problem). For this reason, the knowledge base was structured in a situation-oriented fashion, as shown in Figure 451. The drawback to this structuring is that conclusions about possible consequent dis-turbances must be drawn at the very first level. Thus warm startup, cold startup, and other situations are shown not as consequent situations of an HTF heater failure but as general and equivalent disturbance classes. Technology-oriented structuring makes it possible to include the complete knowledge. Situation-oriented structuring, in contrast, improves the efficiency of knowledge processing for process securing problems in which the focus is on coordination of more than one processing unit.

In general, the final structure of the knowledge base (see Fig. 452) is governed by the procedure learned from the plant operator, by automation theory, and also by the structuring capabilities of the expert system. The reasons for this structure are as follows:

- The decision tree is simplified (fewer levels)
- Knowledge items are represented only once
- Memory requirements are reduced
- Reliability is improved
- The system gains in maintainability

As has been mentioned, each primary cause of disturbances leads to a different decomposition of the technological plant, which logically yields a different structure for the process securing system. For example, consider a vacuum disturbance, which can also be a secondary consequence of a disturbance. The coordinative control action to be generated (see Fig. 452) will depend on how widespread the disturbance is within the chemical section of the plant, which, dynamically and topologically, can be broken down into three subsystems: esterification (S_1), condensation (S_2), and ring-and-disk reactor (S_3). The method of knowledge acquisition is the same as described above for the case of an HTF heater failure.

Figure 450. Technology-oriented knowledge base

The knowledge base for process securing (improvement of process reliability) in the chemical fiber plant includes, for one plant section, some 100 objects (problem classes) in six levels with about 220 process attributes, 40 interference variables as well as process constants, and 500 rules, of which 160 are diagnostic and 340 govern the application of expert knowledge. The expert system developed is coupled to the existing TDC 3000 process control system and

Figure 451. Structure of the knowledge base in the expert system

is in permanent service. Typical response times of the system are in the range of 4 – 10 s; roughly 70 –80 % of the time spent is for on-line acquisition of process data needed for expertise. The development extended over a period of about one year, during which time, 11 experts were interviewed. Figures 453, 454, 455 illustrate the consultation of the expert system by the plant operator.

14. Appendix

14.1. Glossary

Prefatory Note. During the period of transition to a holistic mode of analysis in process control engineering, the terminologies of individual specialties are not adapted to one another, and contradictions may even occur.

The development of an internally consistent, generally accepted terminological structure for process control engineering is a critical and ambitious task. It is the concern of the standardization bodies with jurisdiction over this field.

The following list of terms cannot and is not intended to anticipate such undertakings. The purpose here is to create a unified platform of concepts to serve as a basis for the treatment here. The list defines only a sampling of terms, the ones most important for understanding, and makes no claim of completeness.

The following abbreviations are used:

DF Definition
EP Explanation
LI Literature (references)
EX Example
SN Synonym
CL Classification

Abstraction

DF Abstraction denotes reducing complexity by neglecting all inessential properties or attributes. Which properties and attributes are essential and which can be regarded as inessential will depend primarily on the viewpoint adopted and on the question or problem stated. Both viewpoint and formulation of problem will determine the result of any abstraction.
There are several forms of abstraction:

DF 1 Class-forming abstraction
Class-forming abstraction takes at set of unrelated objects and orders the set in accordance with common properties and attributes. All objects that possess a common set of attributes can be assigned to one class. All objects that belong to this class are referred to as "instances" of the class.

EP 1 Abstraction can take place in several stages.
Associated with any abstraction hierarchy is a taxonomy of concepts or terms denoting the objects in the individual classes.

DF 2 Complex-forming abstraction
Related *objects* can be combined into a *system* with its own characteristic proper-

ties. When unlike objects are joined into a system, the diversity of properties of the individual objects is mapped onto a few external properties of the system. This procedure is called complex-forming abstraction.

SN 2 Special case: Aggregation

DF 3 Functional abstraction
When aggregation is perform, typically not just the complexity of the object but also the level (plane) of examination changes. With every aggregation step, the examination becomes more "abstract" [857]. The levels may be characterized, for example, as physical, operative, tactical, strategic, or intensional. Such a hierarchical structure is also referred to as functional abstraction.

Aggregation

DF Combination of related *objects* into a *system* having characteristic properties. Aggregation is a case of complex-forming abstraction. The objects examined are *classes* or *instances*.

EX By means of assembly, a collection of initially noncoherent objects such as wheels, body, engine, transmission, etc. becomes a system, in this case an automobile. The system exhibits its own characteristic properties, which can only be derived indirectly from the interaction of the element properties. For example, an engine is characterized by the following properties: number of cylinders, way in which valves are operated, number of valves, weight, displacement, etc. The transmission is characterized, among others, by the gear ratios. If the total system "automobile" is examined, the interaction of the properties of the individual elements generates a huge variety of overall system properties. From a given standpoint, however, only a certain subset of these will be of interest. For example, if an automobile is regarded as an element of a transportation system, its behavior can be characterized by a few properties, such as maximum number of passengers, maximum speed, fuel economy, and range. The properties of the individual objects from which the automobile was assembled are no longer of interest.

EP Aggregation forms complex objects by stepwise combination of simple objects.

SN Complex-forming abstraction

Attribute

DF A characteristic or feature of an object (see *Property*).

SN Property

Automatic

DF Performance of a task by a self-contained technical system without outside aid.

LI DIN 19 233

Basic Function

DF 1 Function of process control. Establishment of an independently set process property in a plant section.

DF 2 Functional unit with the capabilities of establishing certain process properties in a plant section. The functionality that a plant section possesses for intervention in the process is disjointly distributed over the basic functions. At a higher level of abstraction, the functionality of a plant section for process control is obtained by superposition of the functionalities of its basic functions.

DF 3 Software/hardware module with the capability of realizing the functionality of a basic function (DF 2) (see also *Functional Unit*).
The term "basic function" is also used with another meaning in process control engineering:

DF 4 In the sense of DIN 19 243, Part 1, basic functions are the smallest building blocks for the acquisition, processing, and output of analog and binary quantities. Here, basic functions include, for example, acquisition via analog input, BCD encoding, and the formation of a reference value.

DF 5 Synonymous with *group control*.

DF 6 Synonymous with *monitoring and control function*.

EP Here, "basic function" is exclusively used in the definitions given in DF 1 and DF 2.

Basic Functional Element

DF 1 Function, element of a *basic function* (DF 1).

DF 2 Functional unit or *functional element* (DF 2) from which a *basic function* (DF 2) is constructed.
In this sense, a basic functional element can be a process intervention, a discrete control device, a group control, or any *functional element* or *functional unit* that is used to construct a *basic function*.

DF 3 Software/hardware module with the capability of implementing a single basic functional element (DF 2) (see note under *Functional Unit*).

Breakdown (Analysis)

DF Elucidation of certain properties of an *object* through a system of simpler objects interacting in an ordered fashion.
The breakdown process is subject to the nesting principle.

EP The system is to be viewed as a model such that, for the question or problem stated, it can explain the external behavior on the basis of the interaction of system elements.
Quite different breakdowns may be obtained, depending on the question formulated and the model selected.

EX An automobile might be broken down
– from the assembly standpoint, into wheels, engine, body, etc.
– from the disposal standpoint, into plastic parts, metal parts, textiles, etc.

Call

DF One-time activation of an algorithm (better: the message that initiates the activation).

EX An analog controller operates continuously and need not be called; a discrete controller, on the other hand, operates under a cyclically (periodically) called algorithm.

Class

DF Group of objects characterized by a set of common attributes.

Command Mode

DF The command mode is a characteristic property of technical units of a command hierarchy. It indicates whether the unit in question receives its control values and commands from the plant operator ("manual" command mode) or from a higher-level technical unit ("automatic" command mode).

Connector

DF Connectors are subobjects of functional modules. Through them, the functional module mediates its message traffic with the surroundings. Each connector thus incorporates certain client and/or server properties of the module in a task-oriented fashion. A connector has an interface to the communications system, its own method for handling the message traffic, and an internal interface with access to the information held and used in the module.

EP Module inputs and outputs, as defined, for example, in the languages of IEC 1131, are special connector types. They serve primarily to handle "get" connections, in which the recipient, through an input, reads information from the output of another module. The IEC languages provide no possibility of handling more complex communications functions (e.g., semaphore-protected write) at the module surface. Separate "communications modules" must be defined for this purpose. With the introduction of connectors, these functions can be incorporated in the semantics of the module (component) language.

LI [858]

Control

The term "control" is used with five distinct meanings:

DF 1 A sequence of action: "Control" or "feedforward control" denotes an open sequence of action over a single transmission element. This meaning is contrasted with "feedback control," which denotes a closed sequence of action.

LI 1 DIN 19 226

DF 2 A binary operation: "Binary control" denotes binary processing of input signals yielding binary output signals.

LI 2 DIN 19 237

EP Here analog processing is contrasted with binary control. There are two forms of binary control: *logic control* and *sequence control*.

DF 3 A functional unit with the capability of performing all functions occurring on a control level (plane, layer). In the control system, it receives tasks from a functional unit located higher in the hierarchy, executes these tasks on the basis of a specified method or recipe, and concludes them by specifying appropriate instructions to the next lower level.

CL *Group control, plant section control, plant control, production control*, etc.

DF 4 Hardware/software modules that realize the functional unit of DF 3 (see note under *Functional Unit*).

DF 5 In a hardware context, a programmable logic controller (PLC).

Control Value

DF A control value is a time-varying setpoint of a controlled *process property*. The expression "controlled process property" signifies that there is a concrete *process control function* that (in normal operation) guides the actual value of the process property so as to track the nominal value in a specified fashion.

EP The control task can be carried out in various ways, for example

– by closed-loop control
– with event-controlled feedback
– by open-loop control

Decentralized Control System

DF 1 Totality of all technical apparatus that makes possible the function "monitoring and control".

DF 2 In a hardware sense, the monitoring and control system is part of the process monitoring and control hardware.

Degree of Automation

DF The degree of automation is the fraction of the process control tasks that is performed automatically by the monitoring and control system.

LI [859]

Device Control Function

DF *Function* for the control and monitoring of devices included in the monitoring and control system but not acting directly on the process. In the case of a sensor, for example, the following functions are carried out: select measuring range, initiate calibration, select place of measurement, etc. In the case of an actuator, the device control functions might include the selection of certain actuator characteristics (e.g., converter), the initiation of a calibration (e.g., metering scales), or the selection of a redundant resource (e.g., dual pump).

EP The functional unit *discrete control device* possesses the functionality to take over the device control function.

Discrete (Control) Device; Discrete Device Technology

DF *Functional unit* with the capability of controlling and monitoring an actuator or sensor. This functional unit generally contains both functional elements for controlling and monitoring the device itself and functional elements for the processing of useful information, for example, to output control commands or to accept and prepare measured values.In the actuator branch, the discrete device acts as a *group control*. Here, the task is to bring about certain process properties in accordance with the specified *control values*.

Element

DF *Object* that is in a well-defined relationship to other objects in the context of a *system* and that cannot or is not to be further decomposed in the context of the present analysis.

EP In contrast to an object in general, associated with an element per se are the relations (relationships, dependences) to the other elements in the system. Certain functions are transferred to an element in the context of the system.

EX A screw in a 100-pack is an object. In a certain system, the screw that holds two parts A and B together is an element of the system. In the system, the *function* "connect A and B" is transferred to this element.

SN System element

Entity

DF 1 A certain state of being of an existing thing; also the thing itself.

DF 2 In connection with object orientation, another name for an object that exists in reality or conceptually and is of essential importance to the problem under consideration. Entities thus form an excerpt of the real world that is necessary for the handling of the problem under consideration. Abstract concepts such as "function" can also be entities.

LI [860]

Entity – Relationship Model

DF The entity – relationship (E/R) model describes the *entities* of an analysis space together with the relations existing between these entities.

EP E/R models are suitable for describing static relations between entities (consists of . . . , is a . . . , is derived from . . .).

EP E/R models in general offer a graphical syntax for the intuitive representation of entities and their relations.

LI [861]

Execution Unit (see also Functional Unit)

DF Execution units are functional units that are capable of realizing a certain role. They are based on resources that possess the required functionality; spatially and logically, they are placed in a suitable layer; and they are configured so that they exhibit the special functionality needed for the role.

EP See *Role*.

SN 1 Device
Here the term "device" should, however, be understood as including units realized logically and in software.

SN 2 Here, execution units are referred to as functional units.

Framework Concept

DF Document describing the structure within which long-term development is to be accomplished.

Function

DF 1 Clearly defined task within a larger totality.
Functions are a separate category of objects.

EP 1 Note: A function is the task proper, and must be strictly distinguished from the capability (functionality) of a unit to perform a task.
In the context of the structure of a system, functions are mapped onto units (*functional units*) that possess the functionalities required for the functions. This transfer makes the units into elements of the technical system, which now implement the functions.
(See also *Functionality, Functional Unit, Element, Substance*).

EP 2 The term "function" is also used informally in relation to concepts that do not have to do with functions (see, e.g., *Functional Unit, Functional Element, Basic Function*; also the commonly used term "functional module" frequently refers to a program module).
Note: Although these expressions are inappropriate with regard to clear categorization of objects, they are not changed here but are used in accordance with common practice.

DF 2 In the process control engineering context, the only other meaning of "function" that is of any interest is the mathematical function. A function is a variable quantity whose value depends in an unambiguous way on the value of certain other quantities. (It is a mapping between algebraically structured sets.)

Functional Element
An ambivalent term denoting both the elements of functions and the elements of functional units.

DF 1 Element of a *function*.

EX 1 Display analog value, transform signal, link values, form limiting value, verify status signal, control valve, block motor, control, . . .

DF 2 Functional unit with elementary functionality.

EX 2 Functional elements, defined as the smallest units of functionality under consideration, include display elements, signal-transforming elements, linking elements, and limit pickups; or, specified from a technological standpoint, process monitoring and control station element, ba-

sic functional element, . . . , motor control, valve control, PID controller, . . .

EP Functional elements can be regarded as the bridge between the top-down analysis of functions and the bottom-up synthesis of functionality. A function must be broken down in such a way that it ultimately consists of functional elements (*Functions*, DF 1), each of which can be fully implemented by functional elements (*Functional Units*, DF 2).

Functionality

DF The capability of an object to perform certain tasks (*functions*).

EP Functionality denotes a fundamental capability of an object and in this sense is a resource. This resource can be utilized by employing the object as an element of a system. In the system context, certain tasks are assigned to the object (as an element of the system). In this way, a part of the functionality of the object is used.

EX A drive, as an object (*functional unit*), has the following capabilities: "can be at a stop," "can turn to the left," and "can turn to the right." The drive M 2 associated with roller R 4 of a roller conveyor has the tasks of turning to the right or of being at a stop. The capability of the object "drive M 2" expressed as "can turn to the left" is not utilized in this system environment.

CL Functionality denotes not an object but a set of properties of an object.

Functional Unit (see also *Execution Unit*)

DF An object with a certain required functionality; that is, an object having certain properties that are necessary for the implementation of the tasks to be performed.

CL Functional units are not functions but play the role of substances. Functional units have the character of resources and can be called on once and only once at any given time.

EX In the planning of a roller conveyor system (see the example under *Functionality*), the system is built up, say, from functional units such as drives, rollers, and so on. These are neither functions nor devices but postulated objects with well-defined functionality. In the planning of the roller conveyor system, these objects, viewed as available resources, are used as system elements; they are combined and linked in such a way that the roller conveyor system as a whole can fulfill the task allotted to it.

EP The definition of functional units is arbitrary. It would be possible to define any functional units with any functionality. It is, however, expedient to choose functional units in such a way that the set of properties (functionality) coincides with, or is a subset of, the property set of available substances. In the software realm, for example, this means that, in constructing a system, functional units may be used only if there are program modules corresponding to them.

Because of the correspondence between functional unit and object, synonymous expressions are used for the two even though this is not wholly correct (see *Function*).

Examples include the expressions "plant control," "discrete control device," "group control," and so forth.

An even more unfortunate situation arises when a synonymous term is used for the function, the functional unit, and the object. This happens with, for example, *basic functions* and *basic functional elements*. Metering is a function; there is a functional unit "metering device" for it; ultimately, there is a software module that implements the functionality of the metering device. In common usage, however, the expression "basic function" is applied to all three objects (see Section 4.5).

EP 1 Examples of the naming of functional units:

Classes of functional units include *production control, plant control, plant section control, group control, discrete device control, basic function*.

Types of functional units include metering device, motor, valve, level control, temperature measurement, reactor control, tower control, and so on.

Instances of functional units include (standard plant and apparatus coding)

motor V 13 R 4 K 12 and level control V 13 R 4 L 6.

EP 2 Here, the expression "functional unit" is also used for a subordinate concept, defined under *Execution Unit*.

Group Control

DF 1 *Functional unit* with the capability of establishing certain process properties in accordance with specified control values. The group control uses internal methods to calculate setpoint values, which it passes on to group controls or discrete control devices at the next lower level.

DF 2 Software/hardware module with the capability of implementing the *functional unit* "group control" (DF 1) (see note under *Functional Unit*).

DF 3 Functional unit with permanently defined, generally applicable control functionality.

LI [862]

Heuristics

DF Doctrine of the methodical acquisition of new knowledge that leads to acceptable results even though not guaranteeing a definite solution of a problem (since there is no proof of convergence). Heuristic procedures are frequently used in the engineering sciences and in operations research.

Inspection

DF Determination and evaluation of the actual state of a plant or apparatus.

LI DIN 31 051 (1985)

Instance

DF 1 All objects that belong to a class are referred to as instances of the class.

EP 1 This definition is general. In a hierarchy of classes, each class can be regarded as an instance of the next higher class. The definition makes no restriction as to the form of class formation.

EX 1 The electric motor is an instance of the class of motors. The asynchronous motor is an instance of the class of electric motors.

A certrain model of motor (manufacturer X, model Z) is an instance of the class of asynchronous motors. The motor with serial number XXX is an instance of a model of motor.

DF 2 Objects representing the lowermost level of a hierarchy of classes. An instance in this meaning cannot be further instantiated.

EX 2 The motor with serial number XXX is an instance in this sense. Every feature, at every time, has a certain expression (serial number, power, construction, voltage, explosion protection, instantaneous rotation angle and rotation speed, . . .).

EP 2 The instance is itself an *abstraction* of the concrete object and takes account only of the properties needed for classification and identification. Other properties of the real object do not become properties of the instance.

EP 2 Note: The instance of a *functional unit*, even though it has many of the same *properties* (*functionality*), is not identical with the instance of the corresponding physical object. They are correlated only temporarily, for the time of installation. If the physical object is removed (for example, taken into the workshop), the two objects may under some circumstances have different relationships.

Instruction Acceptor

DF The instruction acceptor is the connector through which a functional module receives a control instruction.

EP Each functional module can have more than one instruction acceptor.

The control instruction is a command specification with a write character. The instruction acceptor must accept the control instruction immediately after its arrival, independently of cyclic module processing. It checks the content of the control instruction from a formal and a semantic standpoint, sends a reply to the operating system; on acceptance of the command, it writes the new values to the module as effective values.

SN Operator control, control instruction.

Logic Control

DF Control using Boolean logical operations to assign certain output signal states to the input signal states.

LI DIN 19 237

Maintenance

DF 1 Measures taken to keep a plant in functioning condition.

DF 2 Measures to insure the nominal state of a plant.

LI DIN 31 051 (1985)

Model

DF Representation of the important relations between the properties of an object.

SN Model system.

Module

DF In general, a module is an object that forms a closed unit and can be manipulated as such.

EP The concept of "module" should not be further delimited. Subtle distinctions to other concepts, such as block, building block, unit, and so forth, based on the degree of complexity or other attributes, are not meaningful.

SN Apparatus module: device unit
Software module: functional module
Functional module: functional unit

Nesting Principle

DF Specification relating to the *aggregation* of *functional units*. *Instances* of *functional units* are resources that are available once. In the framework of an overall structure, they can be used only once and thus also aggregated only once.

EX 1 If gear Z 1 is installed in gearbox G 1, the gear is no longer available; the gearbox as a whole, however, is still available and can be installed in vehicle F 1. Once this has been done, again gearbox G 1 is no longer available; that is, it cannot simultaneously be installed in vehicle F 2.

EX 2 If a green box is packed inside a yellow box, the green box is no longer available and cannot also be packed inside a blue box. It is, however, possible to pack the yellow box (with the hidden green box inside it) in the blue box.

EX 3 In the case of physical objects, as in examples EX 1 and EX 2, the nesting principle is trivial. The important point is that it also applies to instances of functional units considered as "resources of functionality." If a functional unit A is an element of another functional unit B, functional unit A is no longer available for other functional units (in B, a certain task has been allotted to it that makes claims on its resources).

EP The nesting principle applies only to *instances* of *functional units*. It does not apply to the *aggregation* of *classes* or to the *aggregation* of *instances* of *functions*. A *functional element* can be simultaneously an *element* of more than one *function*.

Object

DF Subject of knowledge, perception, thinking, and action. In the context of object orientation: identifiable patterns that are describable in terms of properties. The internal structure of objects is not directly perceivable but may be deduced from the properties describing the object.

EP Both functions and substances can be treated as objects in this sense [863]. Object is not an antonym of function.

Operating Mode

This term is used with several meanings.

DF 1 Degree of automation of a plant.
Here, the operating mode is the plane (level) of operator control currently selected.

EX 1 A coarse classification includes the following modes: manual, computer, logistical, and automatic [859].

– Manual mode: the monitoring and control system takes over only certain process control tasks for the automatic execution of individual loops.

– Computer mode: the monitoring and control system takes over all process control tasks for the automatic performance of a process section in a plant section.

– Logistical mode: the monitoring and control system takes over all process control tasks for the automatic fulfillment of scheduled orders within a plant.

– Automatic mode: the monitoring and control system takes over all process control tasks including fine production control for the automatic scheduling and fulfillment of orders within a plant.

DF 2 One of the fundamentally different behavior patterns of functional units.

Alternatively, certain technological function units can carry out distinct (selectable) tasks.

EX 2 The functional unit "inert-gas blanketing" has the modes "pressurizing" and "purging." In the first, the task is to establish the pressure in accordance with the specified control value; in the second, to establish the flow of nitrogen through the system.

DF 3 Way in which a plant is run in dependence on the control of the operating value or throughput-to-capacity ratio (startup, normal running, load changing, emergency shutdown, etc.).

LI 3 [862]

Operating Value (Throughput-to-Capacity Ratio)

DF The ratio of product throughput through a plant to design throughput.

LI [862]

Parameter

DF 1 Parameter (of an equation). In functions and equations, an auxiliary quantity appearing alongside the variables proper and either left undefined or held constant.

DF 2 Parameter (of a path or trajectory). Special case of a parameter of an equation.

DF 3 Parameter (of a process). Variable that influences a technical, economic, or other process.

EP In the process control context, this term is often used in an imprecise and poorly understood way, and it should be largely avoided.

Partial Recipe

DF Complete description for making a certain end product or intermediate product in a particular type of plant section.
A partial recipe consists of:

– A specification as to the properties of the inlet products
– A specification as to the state of the plant section at the beginning of the process
– A manufacturing specification for the control of the process.

Phase

DF Phases subdivide *process elements* into a strict temporal order.

EP Each process element, at each point in time, is in precisely one phase. There is no parallelism of phases in a plant section.

EP Remark: In many cases, the phases are named after the unit operations that predominate in them. This often leads to misunderstanding. In a phase referred to as "meter starting substances," the unit operations "meter A," "meter B," "temper," and "mix" (agitate) can take place in parallel. The sequence of phases, however, is strictly serial.

EP The subdivisions of the *phase model* at the lowermost level of refinement correspond to the phases.

Phase Model

DF The phase model is a special network model with which a procedure can be systematically described. The phase model consists of two elements:

– Process elements in which n inlet products are transformed to m end products by means of operations.
– Product nodes with well-defined product properties, which connect the process elements to one another.

EP The phase model offers two substantial advantages:

– Logical network structure
The network structure permits systematic refinement (top-down method) from a coarse structure to a detailed description. The specification of nodes in terms of products makes it possible to describe and refine the individual process elements independently of one another. The phase model is not concerned with the form of the temporal and engineering realization of the coupling.
– The possibility of establishing conditions that must be observed, by specifying profiles of process and product properties in parallel with the design process.
The specification of profiles for the process properties to be brought about in the process elements and the product properties required in the nodes can be done in advance and refined with the network structure.
The phase model is the basis for the construction of quality assurance systems.

LI [859]

Plant

DF Combination of plant sections into a delimited technological unit.

EP The context in which the unit is delimited is not fixed. The important point is that each plant section can be assigned to only one plant.

EP An appropriate delimitation can be found if, for example, the plant is viewed as an analytical space for a fine production control system.

LI DIN 28 004

Plant Complex

DF Organizational combination of plants and other units into an overall heterogeneous unit.

Plant Control

DF Functional unit with the capability of initiating and coordinating the processing elements in the plant sections of a plant on the basis of a specified operating plan.

Plant Section

DF Self-contained unit for the realization of a technical task (see Fig. 26).

EP Among the points characterizing a plant section is that the product treated in it is to be regarded as substantially located in a balance space. This balance space may well be distributed (tower, fixed-bed reactor, etc.) but still forms one unit from the standpoint of process engineering.
Two stirred-tank reactors should be viewed as two separate plant sections because, in general, each is characterized by its own balance space.

LI DIN 28 004

Plant Section Control

DF 1 *Functional unit* with the capability of controlling the *group controls* or *basic functions* of a *plant section* and of automatically controlling a process section in accordance with a specified recipe.

DF 2 Hardware/software module for the realization of the "functional unit plant section control" (see note under *Function*).

Process (General)

DF A totality of interacting trains of events in a system by which matter, energy, or information is transformed, transported, or stored. The smallest unit for analysis is the process element.

EP Note: The term is used to refer to the actual train of events taking place in the real world, not to the system characterized by this process or the specification underlying the process.

EP In a processing system, "process" denotes the dynamic variation of product properties as a result of the action of unit operations or the variation of process properties due to the action of basic functions.

LI DIN 66 201

Process Control

DF Process control takes in all measures that effect the desired course of a process in the sense of established objectives. These measures either can be executed automatically by the process monitoring and control hardware itself, or may have to be performed by human operators.

LI DIN 19 222

Process Control Function

DF *Process monitoring and control function* with the task of influencing the course of a process in such a way that certain *process properties* will track specified *control values*. A process control function is realized by hierarchically structured process control units in the feedforward control branch and a network of process information processing units in the feedback branches (see also *Control Value*).

Process Control Station (Process Monitoring and Control Station; formerly Measurement and Control Station)
The concept of the process control station is a key one in process control engineering. Even so, it is difficult to define and delimit. In common usage, the term refers to a variety of concepts:

DF 1 A point of connection of the process.
In this sense, a process control station is the interface between the process monitoring and control functional unit and an engineering functional unit (used so, at

least in part, in the station data sheet or in the station detail of the piping and instrumentation diagram).

DF 2 A functional unit of process control. This functional unit is characterized by the fact that it possesses at least one process connection point. The task of the functional unit "process control station" is primarily to execute the assigned processing functions (O, I, C, S, . . .). Two remarks should be made, however:

– Only in a few cases is a processing function realized, as a whole, by a functional unit. In many cases (e.g., the S function, central A, I, O evaluating functional units), multiple functional units (and multiple process control stations, in the case of the S function) are involved in realizing a processing function.
– The differentiation between the functional unit "process control station" and more complex interconnections is indistinct (at what complexity does a functional unit with process connection points cease to be a process control station?).

DF 3 A combination of functions. In this sense, the process control station is given by the sum of the defined processing functions assigned to the process connection points (used so, at least in part, in the station detail of the piping and instrumentation diagram).

LI DIN 19 226

Process Control Station Element

DF Process control station elements are the smallest functional units into which a process control station (DF 2) is broken down. Process control station elements have functionality established such that they can be realized by available substances (devices, software modules, etc.). Each process control station element is needed for the performance of one or more processing functions.

Process Element

DF Smallest unit used in analysis of a process.

EP A process element can be realized by a process step or a process section, depending on whether the analysis is time-based or space-based.

Processing Function

DF Term denoting process monitoring and control functions allotted to a process control station. The processing functions are represented in the station detail.

EP Note that a processing function is generally realized through more than one functional unit and, in certain cases, through more than one process control station, despite the unambiguous allocation (see note under *Process Control Station*).

Process Intervention

DF Monitoring and control functional unit that combines all functional elements (process control station elements) of control hardware between discrete control device and process.

Process Monitoring and Control Function

DF *Function* realized with the aid of the monitoring and control hardware. In general, monitoring and control functions are closed lines of action between process elements, between operator and process, between operator input and operator output, or in general the response of the outputs of the process control system to certain input signals.

CL Monitoring and control functions in process control engineering can be specified by control action in the following ways (among others):

Process control functions

– After operation DOS_3_ON, meter in x liters in t minutes
– After operation T5_ON, turn on plant section 5

Process securing (stabilization) functions

– If temperature T 15 > 80 °C, turn off pump 3

Process information functions

– Display temperature T 15 in on-screen flowsheet

Device control functions

– Calibrate pH probe Q 14

System control functions

– Select screen page plant section ST 3

Monitoring and control functions also occur in other settings such as manufactur-

ing engineering or building management engineering.

Process Monitoring and Control Hardware

DF All devices employed for the task of process monitoring and control.

LI DIN 19 222

SN Process control system

Process Property

DF Process properties are the categories of information about a process. They include state variables, process parameters, control variables, setpoint parameters, and process indicators.

LI [864]

Process State

DF Expression of the process property vector at a given time (see Section 11.3).

EP See also *Quality*.

Production Control

DF 1 Functional unit with the task of scheduling production requirements, preparing a production schedule, allocating the needed resources, and monitoring the performance of the schedule.

DF 2 Software/hardware module with the capabilities of realizing precisely the function "production control" (DF 1) (see note under *Function*; see also Fig. 31).

Product Properties

DF Product properties are the categories of information about a product. They include physical quantities, chemical quantities, technological properties, and product indicators.

LI [864]

Project

DF Expressed generally in the terminology used here, a project is the complete temporal framework of conditions governing all *substances* for the realization of tasks represented by *functions*. The substances consist of procedures, systems, and elements (see Figs. 10 and 65) and are also referred to as resources.

Property

DF A characteristic or feature of an object. A property consists of the type of feature (category, size) and the expression of the feature (intensity, value). The type of expression (metrical, topological, etc.) depends on the type of feature.

EX A house might have the properties
Type of feature: Expression:
Address Hauptstraße 3
D-11111 Kleinhausen
Owner Mrs. Meier
Height 8.25 m
Building style Jugendstil (Art Nouveau)

EP Classes are marked by common feature types. The expression is an instance quantity.

SN *Attribute*

Quality

DF Expression of the product property vector at a given time (see Section 11.3).

EP See also *Process State*.

Recipe

DF A recipe consists of the sum of the partial recipes needed to make an end product and the explicitly stated relationships between the partial recipes.

EP The term "recipe" has been introduced but is still subject to various interpretations. "Production instructions" or "production specification" would be a more precise term and should be given preference in the future.

Redundancy (General)

DF 1 Concept in information theory, denoting that a message contains elements that can be omitted as not providing any additional information but merely supporting the desired basic information.

– Beneficial redundancy: constituents that can be omitted would back up the information if other constituents were omitted.

– Empty redundancy: constituents that can be omitted would not back up the information content if other constituents were omitted.

DF 2 Severalfold presence of a functionality in order to enhance the availability of a function.

Redundant Measurement

DF The measurement of a certain process property is said to be redundant when the actual value of this process property can be acquired from at least two disjoint groups of available measurements.

EP If a measurement becomes unavailable, the disjointness means that only one group is affected, and the actual value continues to be available to the system. This is an example of beneficial redundancy.

- Homogeneous redundancy: the actual value of the desired process property is determined by using the same measuring principle and by multiple measurements of the same auxiliary process properties.
- Diversity: the term "diversity" (diverse redundancy) is used when:
  - The actual value of the desired process property is determined from measurements of different auxiliary process properties (example: determination of flow rate via pressure drop and with magnetic flowmeter).
  - The actual (instantaneous) value of the desired process property is determined on the basis of the same auxiliary process properties, but the auxiliary process properties are measured by different methods (example: level measurement with float and ultrasonic instruments).

Repair(s)

DF The restoration of the nominal condition of a plant.

LI DIN 31 051 (1985)

Requirements (see also *Specifications*)

DF Document describing the tasks (*functions*) that are to be implemented in the framework of a project. The initial description is solution-invariant.

SN Bidding specifications

Role

DF Roles are unambiguously described tasks within a larger context. The realization and performance of a role requires a functional unit (execution unit), which realizes the role in a certain layer at a certain time.

EX The relationships between roles, resources, functional (execution) units, and layer can be illustrated with three examples:

– Theatrical performance
Consider the role of "Gessler" in the play "William Tell" (virtual system).
The realization of this role demands an actor. Any actor who knows the text and is capable of playing Gessler is a potential candidate and thus belongs to the pool of resources. Now suppose the play is to be performed on October 16, 1995, at venue X. The role system thus requires that an actor suitable for the representation of Gessler be available at X on October 16, 1995. For the theater manager, this means that an actor Y must be sought and signed for the performance; that is, a resource must be selected and allocated. This can take place ahead of time when the theater season is being planned. For the play to be actually performed, it is important that Mr. Y be available and prepared for the role at X on October 16, 1995. He is configured for his role through makeup and appropriate costuming. Mr. Y is then an available function (execution) unit for the role of "Gessler" at X on October 16, 1995.

– Hardware component
Consider the following role: discrete control component for reactor X. It belongs to the process monitoring and control system being planned (virtual system). Each component of type Y made by manufacturer A possesses the required functionality and is thus a potential resource. As a functional (execution) unit, it is present (available) if, as a hardware part, it has been delivered, configured (e.g., jumpers placed), and installed in the proper slot. (This job is performed by installation.) In this state, the component can take over the role envisioned for it in the process monitoring and control system.

– Motor control module
Consider the role of the control of motor V 12 TA 45 K 2. The process control being designed is the virtual system. For the realization of the role, a software module must be placed in the process monitoring and control system and made available as a functional (execution) unit. Any

instance of the motor control type MOT becomes a candidate. Thus, an instance MOT–V 12 TA 45 K 2 is defined, configured (here this may mean parameter assignment: number of feedback messages, startup time, etc.), and installed in the component provided (which here corresponds to the layer). Now this software module is capable of realizing the role of the motor control V 12 TA 45 K 2.

SN Function

Securing (Stabilization) Functions

DF *Functions* for preventing unacceptable deviations of the *process,* of the *process control,* or of the *process monitoring and control hardware* from the nominal state. Securing functions do not intervene in the sequence of events under normal operating conditions and permit the *process control functions* to perform their task. Before a deviation enters the unacceptable range, the securing functions are activated, interrupting the access of the process control functions.

EX Typical securing functions are interlocking of functional units and STOP conditions in sequence controls.

EP Other expressions of this concept refer to improving or enhancing the reliability or safety of the process.

Sequence Control

DF *Control* in which the program is constrained to progress step by step and the advance from one step to the next step in the program depends on advancing conditions.

LI DIN 19 237

Depending on the type of conditions for advance, the sequence control is said to be time-dependent or process-dependent. One also speaks simply of timed control or event control.

Specifications (see also *Requirements*)

DF 1 Document that contains all information required for the realization of a certain system.

EP 1 The specifications describe how the functionality of a system as set forth in the requirements can be realized with the help of given resources. "Given resources" mean functional units to be used, objects (hardware/software) to be used, rules and procedures to be applied, and constraints to be observed (e.g., limitations on time, money, material, space, and personnel resources). The specifications are linked to the solution adopted.

DF 2 Separate document describing the constraints, rules, and data that must be followed in the procedure.

Substances

In philosophy, the concept "substance" is employed with a variety of meanings. Here it is used in the sense of CASSIRER [863]:

DF Substances are objects in the real world that can be described and identified in terms of attributes.

Substances either are real objects themselves or correspond virtually to real objects.

Functions always require appropriate substances for their realization.

EP Substances include systems and their elements (devices), as well as skills and methods (procedures). With the aid of procedures, functions are realized from systems and their elements through the use of a part of their properties.

Of the great number of possible substances (see Fig. 9), "standards" (e.g., design, installation, and hardware standards) are derived by means of appropriate definitions. Substances, as real objects, can be either hardware objects or software objects.

Subsystem

DF Part of a *system*, having the following properties:

– Elements of a subsystem are always elements of the surrounding system as well.

– The relationship between elements in a subsystem always corresponds to the same relationship between the same elements in the surrounding system.

– Distinct subsystems of a system can overlap.

EP A special case is the complete subdivision of a system into nonoverlapping subsystems. This case corresponds to a *break*

*down*in accordance with the *nesting principle.*

LI [865]

System

DF A delimited, ordered totality of interacting subsystems or system elements. This configuration is separated, or regarded as being separated, from its surroundings by an envelope.

EP One characteristic of a system is that it simultaneously admits of an external and an internal view.
In the external view, the system is examined from outside its envelope, which is thought of as opaque. The system behaves as an aggregated object (black box).
In the internal view, the system is examined from inside its envelope, which is thought of as opaque. From this standpoint, the structure and mode of operation of the system can be seen.
The properties of a system cannot generally be elucidated by superposing or aggregating the properties of its elements.

EX A gearbox is a system of gears, locking mechanisms, bearings, and shafts. From the outside, in the technological view, all that is interesting about a gearbox is the transmission ratio between the driven shaft and the driving shaft. The internal geometry and the number of gears are not important. From the inside, on the other hand, it is precisely the geometrical structure of shafts and gears that is of interest. The only way to determine the transmission ratio effective at the envelope is through a complicated computation based on the individual gears of the active branch.

EP It is important that a system admits of both views at the same time. It can be said to represent an object at the moment of aggregation or disaggregation.

LI DIN 66 201, DIN 19 226, [859]

Taxonomy

DF A methodology used in science, consisting in the assignment of concepts or individual phenomena to a general ordering scheme.

Type

DF Class whose objects exhibit a high degree of interrelatedness.

Unit Operations

DF The smallest physical or chemical operation performed, which acts on a material system in a plant section.

EP By means of physical or chemical operations, the material system in a plant section is transformed from a state A to a state B. These operations can be broken down into unit operations. As a rule, unit operations are carried out one after another, but there are unit operations that take place in parallel. Examples: conveying and drying in the pneumatic conveying dryer, reaction and mixing in the stirred-tank reactor, etc.

CL Unit operations can be classified under conveying, mechanical processes, force-field processes, processes with molecular driving force, and chemical processes.

ECITC	European Committee for Information Technology Testing and Certification
EEPROM	Electrically Erasable Programmable Read Only Memory
EIA	Electronics Industries Association
ELCS	Extended List of Control Software
ElexV	Verordnung über elektrische Anlagen in explosionsgefährdeten Räumen
EPROM	Erasable Programmable Read Only Memory
EPS	European Physical Society
E/R	Entity – Relationship
ESPRIT	European Strategic Program for Research in Information Technology
ETSI	European Telecommunications Standards Institute
EUREKA	European Research Coordination Agency
EXERA	Association des Exploitants d'Equipement de Mesure, de Régulation et d'Automatisme
FIP	Factory Instrumentation Protocol
FLAVOR	Programming language
GA	Gateway Functions
GI	Gesellschaft für Informatik
GMA	VDI/VDE-Gesellschaft für Meß- und Automatisierungstechnik
GMD	Gesellschaft für Mathematik und Datenverarbeitung
GMR	VDI/VDE-Gesellschaft für Meß- und Regelungstechnik, (now: GMA)
GVC	VDI-Gesellschaft Verfahrenstechnik und Chemieingenieurwesen
HART	Highway Addressable Remote Transducer
HD	Harmonization Documents
HDLC	High Level Data Link Control
HHT	Hand Held Terminal
HPC	Human – Process Communication
IEC	International Electrotechnical Commission
IECEE	IEC Sub-Committee: Conformity Testing to Standard for Safety of Electrical EquipmentI
IEEE	Institute of Electrical and Electronics Engineers
IFAC	International Federation of Automatic Control
IFC	International Fieldbus Consortium
IFIP	International Federation for Information Processing
IFORS	International Federation of Operational Research Societies
IMACS	International Association for Mathematics and Computers in Simulation
IMEKO	Internationale Meßtechnische Konföderation
IMC	Internal Model Control
IMS	Information Management System
IP	Input Product

ISA	Instrument Society of America
ISDN	Integrated Services Digital Network
ISO	International Organization for Standardization
ISP	International Systems Project
LAN	Local Area Network
LISP	List Processing Language
LLC	Logical Link Control
LTR	Loop Transfer Recovery
MAC	Medium Access Control
MAP	Manufacturing Automation Protocol
MIS	Management Information System
MMC	Man – Machine Communication
MMS	Manufacturing Message Specification
MODEM	Modulator and Demodulator
MPC	Man – Process Communication
MVS	Multi-Virtual System
NAMUR	Normenarbeitsgesellschaft für Meß- und Regeltechnik in der chemischen Industrie
NIR	Near Infrared
OOA	Object Oriented Analysis
OOD	Object Oriented Design
OP	Output Product
OS	Operating System or Open System
OSF	Open Software Foundation
OSI	Open Systems Interconnection
P	Proportional (controller)
PBX	Private Branch Exchange
PC	Personal Computer
PDS	Plant Design System
PDU	Protocol Data Unit
PI	Proportional Integral(controller)
PID	Proportional Integral Differential (controller)
PL/1	Programming Language Number 1
PLC	Programmable Logical Controller
RFN	Reversed Frame Normalizing Process
PROFIBUS	Process Field Bus
PROLOG	Programming in Logic (programming language)
PROM	Programmable Read Only Memory
PTB	Physikalisch Technische Bundesanstalt
RAM	Random Access Memory
ROM	Read Only Memory
ROI	Return on Investment
SA	Structured Analysis
SADT	Structured Analysis and Design Technique
SAP	Service Access Point
SAS	Statistical Analysis System, Statistikprogramm der Firma SAS Institute
SIREP	International Instrument User's Association
SNA	Systems Network Architecture (IBM)
SPARC	Standards Planning and Requirements Committee (RISC Architecture)
ST	Structured Text
STEP 5	Programming language
SQL	Standard Query Language
TC	Technical Committee (IEC)
TIRC	Temperature Indicating Recording Controlling (DIN 19 227)
UNIX	Multitasking and Multiuser operating system
UTE	Union Technique de l'Electricité
UVV	Unfallverhütungsvorschrift
VbF	Verordnung über brennbare Flüssigkeiten
VCI	Verband der Chemischen Industrie
VDI	Verein Deutscher Ingenieure
VDE	Verband Deutscher Elektrotechniker
VIK	Vereinigung Industrielle Kraftwirtschaft
VLSI	Very Large Scale Integration
VMD	Virtual Manufacturing Device
VMS	Operating system from DEC
VOB	Verdingungsordnung für Bauleistungen
WAN	Wide Area Network
XP	Expert System
ZVEI	Zentralverband Elektrotechnik- und Elektronikindustrie

1. Introduction

With the growing concern in society as a whole about the form the future will take, ethical aspects have acquired increasing significance for the chemical industry. They center on the responsibility of employers and the principles governing their actions. This is because a wide variety of complex questions exist – not only in the interaction between companies and their social and economic environment, but also within the companies themselves – which have considerable bearing on the fields of ethics and morality. Some time ago, such topics of discussion generally received little attention. This changed at the latest by the 1980s due to increased awareness for the environment and for life in general. Questions of responsibility have been integrated into society and industry following calls to align corporate activities not only with the present generation, but also increasingly with future generations. The central question is therefore: How can we make sure that the possibilities for development available to future generations are not restricted by our present-day actions? This is an important requirement within the framework of the idea of "Sustainable Development", as resolved with worldwide consensus at the environmental conference in Rio de Janeiro in 1992 (see Section 4.1) [1]. This resolution contains an unambiguous appeal to our responsibility to conserve the environment, to use its resources sparingly, and provide society exclusively with production processes and products which stand up to an examination of this kind. Today, it is not only technology itself which is at the center of criticism, but also its products. One aspect focuses on weighing up chances and risks for humans and the environment. An important concept is that ecology, economy, and social matters have equal ranking.

The call for Sustainable Development is linked closely with ethical considerations, because it asks questions about the behavior and responsibility of people in the present, but with a view to the future. Its implementation in the chemical industry is largely in the hands of science. The special consideration of the chemical industry is not just a matter of chance; because of its experience and know-how, the chemical industry has the potential to influence production and products in the sense of the abovementioned sustainability. However, its contribution should only be regarded as a partial solution, because Sustainable Development is influenced by many factors that are closely interlinked. Apart from this, the call for equal consideration of economy, ecology, and social matters ne-

cessitates optimization of the overall structure. All sections of the human community (producers, customers, consumers, etc.) must contribute to this. Since the chemical industry, as part of the overall system, extends into all three areas, its contribution must be seen against the background of their historical development and the history of paradigms.

2. Structural Change and Change of Paradigms

2.1. Chemistry and Industry

Striving to understand the processes of nature and exploiting them to improve the standard of living has accompanied the history of mankind since its earliest beginnings. Chemistry as a natural science sprang from this endeavor in close connection with the dominant *Weltanschauung* of the respective epochs. In the beginning, much practical knowledge about the characteristics and effects of natural substances was acquired by simple experimentation. This led to the production of commodity articles and the ability to distinguish between poisonous substances, medicinal substances, and foodstuffs. Dyes and ceramics are regarded as the oldest products of humans. Technology was given a particular stimulus by the development of metallurgy, and mention should perhaps also be made of glass production, tanning, soapmaking, and of foodstuffs like beer, wine, and sugar. One of mankind's major challenges was, and still is, not only to use natural substances but to redesign and manufacture substances himself. With increasing know-how and experience, chemistry become a systematic and exact science which, step by step, created the basis for the achievements of modern times and the commercial application of scientific findings.

Modern-day chemistry and its industrial significance only really began about 200 years ago with, among others, the production of soda and sulfuric acid in the late 1700s and early 1800s (inorganic chemistry). Other key steps included the discovery of coal-tar dyes, the development of organic chemistry (from 1850 onwards), and polymers and plastics in the 1900s. Fundamental discoveries and their development into industrial processes broke fresh ground and provided the potential for major qualitative advances. The success created a conception of chemistry that was characterized by a belief in progress and a demand from the marketplace.

The number and quantity of products and their consumption rose dramatically. Thousands of materials are nowadays manufactured on an industrial scale. The products generated by the chemical industry are now found in all walks of life, and it is impossible to imagine everyday life without them: examples are pharmaceuticals, textiles, dyes, plastics, coatings and engineering materials, developed specifically for applications in the construction industry, the home, transport, food, sport, leisure, medicine, etc.

As regards chemistry's dynamism of development and its self-conception, the environmental aspect tended to take a back seat to what could best be described as a unidimensional aim to achieve progress until the second half of the twentieth century. It was only with the strong upswing in the chemical industry in the 1950s, which led to significant impact of production on the environment (air, water, soil), that the need arose to take countermeasures. Being evidently a technical problem, it was tackled with the aid of technology where the problems manifested themselves, that is, at the end of the production process, and this led to the birth of end-of-pipe environmental protection. This provided for the treatment of wastewater, solid waste, and waste air in large, mostly centralized facilities such as wastewater-treatment plants and incinerators. These end-of-pipe measures produced success in a relatively short time, and made an important contribution to improving the environmental situation in the 1970s, for example, in Germany. In subsequent years, both for technological and for economic reasons, a structural change has been taking place throughout the chemical industry from end-of-pipe environmental protection to preventive, integrated environmental protection (see Section 5.1.2).

The chemical industry today operates globally. As a supplier to many other branches of industry, it is part of the economic chain and intricate social inter-relationships. The degree of interlinking is very high indeed. Structural changes in the chemical industry have numerous implications for the structure as a whole. Globalization and the interlinking of

present-day markets necessitates a holistic approach, in which a partial optimization (ecological/economic/social) can have a negative effect in the long term.

2.2. Social System

Industrial development over the last two hundred years is marked not only by technical and economic innovations. It has also been accompanied by a wide range of social changes that have affected man's conception of himself. Increasing mass production and mounting consumption, a high standard of living, high division of labor, and specialization of skills and know-how, an increasing flow of information, greater mobility, and so on, have gone hand in hand with the opening up of new markets and the creation of new branches of industry, areas of work, and professions. The level of interaction and interlinking has increased enormously in all areas of life and work, especially in the highly industrialized societies. Above all, the far-reaching developments in electronics (e.g., computer and satellite technology) have brought profound, as yet, not entirely foreseeable changes, and have exerted an influence right the way down to our way of thinking. Many processes have been accelerated and expanded. For a long time, the maxim was "higher, further, faster". Traditions were frequently challenged or even broken. Fundamental rules which were embodied, for example, in religion, morals, and legal systems, lost their validity. Adjustment and rethinking processes were needed.

New technologies with a deep level of penetration were installed. As a result, the radius of action of the companies increased, but so did the possibilities of individuals to liberate themselves from the constraints of nature with the aid of technology. However, this was accompanied not only by benefits and greater freedom. New dependences came into being, which resulted from the way our present-day life is organized. For example, modern means of transport and traffic routes have made it possible to separate the place where we live from the place where we work. However, we have as a result made ourselves dependent on reliable, flexible, and inexpensive means of transport. Another example is the far-reaching division of labor: humankind is nowadays increasingly less in a position – either technically or from the organizational viewpoint – to produce its own clothes and feed itself. Life, also that of the individual, nowadays takes place more on the basis of interpersonal and social agreements. People are dependent on the specialist knowledge and skills of experts. An important factor here is trust in the work of another. This dependence, however, generates a subliminal insecurity, because man is no longer able to control many components of his life himself.

There are other dependences, too: the standard of living in the highly industrialized societies grew in the second half of the twentieth century to such an extent that the elemental needs of man (food and somewhere to live) were essentially satisfied and were no longer regarded as vital needs. This opened up the possibility of shifting human needs to a higher plane. In line with Maslow's hierarchy of needs, new qualities came along which had to be fulfilled, such as leisure, self-realization, craving for admiration, etc. This has progressed so far that, in a highly industrialized society, the benefits of many products of the chemical industry are taken for granted. The negative effects of industrialization and technology are no longer tolerated. Today, a high, perhaps exceedingly high, level of safety is demanded; risks are rejected entirely. The logical consequence of this approach is that chances are lost, because chances and risks are closely linked to one another.

The technical/economic differentiation in the highly industrialized countries has created a variety of life styles and criteria of values. With regard to the future alignment of society, this pluralism is a factor which should not be underestimated, and one which increases the level of difficulty of future solutions.

2.3. Environmental Awareness

There is no doubt that the chemical industry has played a major role in the appreciable improvement in the standard of living and life expectancy of man, and that the western world is today living at a very high standard. Practical reality has, however, shown that the achievements of the chemical industry cannot have only advantages,

but also disadvantages for mankind. These include negative effects of production facilities on the environment (solid wastes, emissions, accidents) and the interaction of products with the environment and, in some cases, undesirable effects on human health. Yet negative effects such as these are not a phenomenon of the modern age. Throughout history, man has intervened in many different ways in the natural balance, and in some cases caused considerable changes. An example from the ancient world is the salization of Mesopotamia, and from the pre-industrial age, the deforestation in the Mediterranean region and the contamination of waterways by tanneries. However, for long time, the effects of human actions were limited to local, or at most, regional areas and were often reversible. The depth of technical penetration was insufficient to have broader implications. Processes of change proceeded relatively slowly and their range of action was fairly small. Today, however, the scope for human activity has attained a global dimension, which means that the consequences are far more interlinked and, as a result, may also become irreversible. Apart from the space aspect, there is also the time-related long-range effect.

The first major wave of events that alerted the public to the impact of industrial developments – especially those in the chemical industry – on the environment came in the 1950s and 1960s, when the effects of large-scale chemical production became apparent. At that time, however, this did not provoke any general discussion. The desire for the consumption of products that improve the standard of living was still the priority for most people. The chemical industry was not generally challenged, nor was its technology or its products. Although there was little public discussion, specialists began debating the problem back in the 1950s, and this debate gradually intensified as scientific knowledge grew, particularly in the field of (environmental) analysis. In parallel with this, scientific findings were collected about substances and products, with the result that the substance or product-related aspect was added to the environmental-segment-related approach, which was formerly directed primarily at the effects of the production processes. Following on from this, a broad international exchange of views among experts relating to the production and products of the chemical industry was initiated, which expanded over the next few years to include society as a whole, and which has resulted in present-day discussion.

Ethical aspects also became increasingly involved, all the more so as negative effects of chemical production became apparent, such as the impact on the environment of solid waste, wastewater and waste air, harmful side-effects of products, and chemical accidents. Because of the high consumption of resources in the industrialized world, questions were also raised about limitations to growth [2]. This development was accompanied by the mounting interest of the media in environmental topics, and partly also by the formation in the late 1970s of environmental groups calling for a change in the ecological awareness of society. Consequently, since the beginning of the 1980s, people throughout the world have become increasingly sensitive to environmental matters and to the risks generated by the production processes and products of the chemical industry. On some occasions, this progressed to such an extent that some groups wanted to do away with production but were not willing to do without the products. The situation was accompanied by a mounting scepticism towards technology (ranging from a vague uneasiness to demands for abandonment) and a growing, sometimes utopian call for absolute safety. The belief in traditional progress, based solely on technology, has been significantly relativised as a result. The evaluation of technology became a programmatic concept.

Growing environmental awareness was connected with the call for a form of environmental protection which penetrated all areas of life, and which, in some cases, assumed the character of a moralistic ideal and, at its climax, even manifested itself as *Zukunftsangst* (fear of the future). Discussion in western societies is nowadays characterized by the question of what kind of progress man needs and what he can accept responsibility for.

3. Ethical Aspects

The chemical industry is embedded in the social currents with their ecological, social, cultural, and political aspects. It must take into account and evaluate not only these developments, but also its own experience and know-how to make decisions for the future. The resulting activities

in turn have consequences. Since ancient times, the question "How should man act?" has been at the center of ethics (Greek: *ethos*), the philosophical science of morality [3]. Ethics, as the theory of values and norms, is nowadays often regarded as being synonymous with moral philosophy. The term moral (Latin: *mos*), which is often equated with ethics, should be understood in its meaning of morals in their entirety, as the practical application. Generally, ethics involves the question: To which values and norms, goals and objectives should man orientate his activities? The main subject of the ethical approach are human activities, with the accent either on the character from which these arise ("Gesinnungsethik"), or on the effects generated by them ("Erfolgsethik"). Ethical thinking also deals with the question of whether the moral willpower and esteems are innate, and thus, to a certain extent, common to all mankind, or whether they are gained from experience, and thus change from people to people and from era to era. Over the course of time, depending on the starting point of the approach, many different variations in the direction of ethics have been created.

The social way of thinking has changed over the course of time. Ethical reflection began in ancient philosophy with Socrates and Plato. Through Aristotle, it became a science of its own. Conceptions and analyses of these ancient thinkers have been influencing philosophy and thinking right through to the present time, and have consequently also influenced the course taken by man's understanding for nature and science. Other famous personalities like Galileo, Descartes, Kant, Hegel, and Schweitzer also contributed new or opposing aspects and findings (ethics of discourse, duty, virtue, utility, reason, etc.). They made a major contribution to the change in the paradigm. An admiration for nature alternated with a contempt for it and its exploitation. Man's relationship with nature ran in parallel with this, and his relationship to technology and the development of western culture was also shaped by philosophers. The modern technology of the present industrial countries can be seen as the offspring of the Renaissance. Technical procedures and the basic approach and attitude were decisively influenced by the philosophers Bacon and Descartes. Bacon developed the inductive method in science. He had the vision of expanding scientific knowledge to such an extent through rationally planned empiricism that man would acquire control over nature. Descartes developed Bacon's approach further. He saw man as a subject who had at his disposal everything else as objects. This had a major influence on the philosophy of technology.

There is, as yet, no conclusive answer to the question of man's relationship with nature. The duality of the object to be exploited and the subject to be protected is still evident today in the way the western world sees nature. This question, together with the fact that modern technology has resulted in activities of a new dimension, with new consequences, has led to the formation of one of the "new ethics", namely, "environmental ethics". This states that ethical decisions should involve the whole of humankind, include the future, and take appropriate account of ecological matters. All in all, it is a question of developing suitable ways for humankind to handle nature. For this, it is useful and indeed essential to have moral principles for such behavior. This, in turn, leads to questions about man's role in all this. Depending on the standpoint, a distinction can be made between anthropocentric (centering on humans), pathocentric (humans and animals are equal because of their capacity to suffer), biocentric (all types of animate nature are equal), and holistic (regarding animate and inanimate nature as a complete structure) environmental ethics. Human dominance is up for discussion. Many articles have been published on environmental ethics. All thoughts on this subject probe the emergence of environmental problems and seek a strategy to overcome them.

The philosopher Jonas developed the challenges of modern technology for the ethical orientation of human action into a theory of extended responsibility [4]. He regards ethics as no longer being confined to the immediate vicinity, with regard to time and space, of activities, but feels that present-day ethics should take into account the global conditions of human life, and, at the same time, attend to the distant future. He takes this right through to the question of the continued existence of humans as a species. In other words, ethics has to deal with activities which extend further into the future than ever before. A central question here is the aspect of irreversibility. Jonas' principle of responsibil-

ity should be used to slow down human activities and thus put a brake on the "Promethean-utopian creative urge". Jonas used as his compass the preconceived risk and the fear associated therewith. The change in the range of responsibility is, for Jonas, the central point of his ethics of the future, and it includes not only the future of humankind but also the future of nature.

It is certainly undisputed that humans should not be allowed to do everything they are technically capable of doing. However, they should not be excessively restricted in creating something new, because technology offers the chance of realizing Sustainable Development. Dispensing completely with technology is therefore just as harmful as using it unrestrictedly. The aim should be to act responsibly with a preventive approach. Standards or yardsticks are required for this, but they cannot be set by scientific knowledge alone. Today, more than ever before, an interdisciplinary, holistic approach is needed. This includes eliminating the sometimes exaggerated separation of the humanities from the natural sciences. The existing conflicts must be broached. For example, natural science, which is characterized by experimentation, must, because of the inductive methodology, get to grips with the reproach that, although it produces knowledge, it does not produce the necessary cognition. Discussion of the two directions is particularly important with regard to sustainability's call to give ecological, economic, and social matters equal ranking. There is no doubt that we need a new dimension and quality of human sense of responsibility which leads to a modern ethics of responsibility.

4. Chances for the Future

4.1. Concept of Sustainable Development

Against the background of a dynamically growing world population, limited natural resources, the sensitivity of our ecosystems, and lack of food for many peoples of the world, discussion about the further development and responsibilities of humankind today is characterized by the term "sustainability". This term is not new. It was used back in the early 1700s in German forestry parlance. It referred to the principle that utilization of a renewable resource such as a forest must not occur faster than the rate of regeneration of that resource. The term sustainability was extended to cover other natural resources (e.g., fisheries) and is becoming established worldwide. The concept of forestry management, which was originally primarily an economic one, was supplemented over the course of time by ecological aspects, and has ended up today more as an ethical matter. The term "Sustainable Development" was mentioned for the first time in 1980 in the World Conservation Strategy of the International Union for Conservation of Nature and Natural Resources (IUCN). In 1983 it was defined as follows in the UN-appointed World Commission for Environment and Development, chaired by the Norwegian politician Brundtland: "Sustainable Development is development that meets the needs of the present without comprising the ability of future generations to meet their own needs."

The Brundtland report *Our Common Future*, published in 1987, encouraged worldwide discussion on Sustainable Development [5]. It reached its temporary climax in 1992 at the UN Conference on Environment and Development in Rio de Janeiro [1]. There, Sustainable Development was unanimously declared the common aim and the guiding principle for national and international environment and development policy. It was defined in more detail in the so-called Agenda 21 [1], [6]. This lists, among others, measures for its concretization and a call for its implementation. It gave as one of the key requirements for achieving the goal of Sustainable Development, nationally and internationally, that the measures take equal regard of ecological, economic, and social matters. These three pillars for continued existence in the future substantiate the call for ethical responsibility. This means that, apart from the economic questions concerning the efficient allocation of goods and resources, they should also include not only ecological problems such as the shortage of resources and environmental pollution, but also social problems such as hunger, poverty, and disease, in order, for example, to also find solutions to the questions of justice between the rich "north" and the poor "south" (intragenerative conflicts) or between present-day and future generations (intergenerative conflicts). All sec-

tions of the human community must face up to this challenge. The UN Commission on Sustainable Development (CSD) has the job of monitoring the implementation of Agenda 21.

Nevertheless, it must be said that a comprehensive sustainability concept of this kind with the triad of ecological, economic, and social aspects contains a contradiction and, in many cases, an almost insoluble conflict of objectives. In any case, all the different approaches make it necessary to take a very wide-reaching, interdisciplinary view.

The idea of Sustainable Development is thus a call to integrate [7]. Ecology, economy, and social matters should continue to develop together in such a way that, in a longer term, none of the three areas is irreversibly damaged. The concepts dealing with the ways of implementing Sustainable Development and its content and objectives differ considerably. This is due to the complexity of the questions and the plurality of the world's societies. Yet we should not expect any simple, uniform solutions. Sustainability can neither be centrally predetermined nor scientifically derived and quantified. This is not possible for one thing because the needs of future generations can only be defined to a limited extent. Ideas of what sustainability is are, to a very large degree, time, situation, culture, and knowledge-dependent, and are subject to constant change. For example, it is not possible to conclusively answer the question of which raw materials should now be conserved for the future, and in what quantities. The basic idea of Sustainable Development, on the other hand, is to avoid narrowing the chances for future generations. The demand that sustainability should be understood in a naive manner, in line with the early considerations on forestry management, would certainly not be adequate today. Instead, the call for sustainability must be seen as a regulative idea, comparable with other major concepts like freedom or justice. Ideas such as this prescribe directions and name goals. Searching and learning processes in the various sections of society must be oriented to it, and it must be understood as a communicative task which encourages motivation and the willingness to participate. These are protracted processes that will never be concluded, because new findings will repeatedly make course corrections necessary in a continuous process of improvement. In other words, Sustainable Development can only be the result of a permanent social searching and learning process. As part of the overall system, the chemical industry has adopted the idea. In its implementation, it focuses on self-responsible actions, coupled with self-imposed commitments and co-operation. Sustainable Development is not a self-contained concept for action, but a framework for designing the future.

4.2. Dialogue

From the open conception of the idea of Sustainable Development and its integration principle there arises the direct necessity for social communication processes. With regard to the equality of ecological, economic, and social matters, these processes must contain interinstitutional and interdisciplinary discourse. However, this is only possible if the habits of demarcation and self-imposed isolation of individual institutions and specialist disciplines (which have grown with industrialization and are based on different sets of logic for action and regles du jeu and their own semantics) are broken down. The implementation of this idea must be a central goal of the integration concept. Communication is the hinge that can bring opposing points of view together.

Target-oriented communication is based on knowledge and understanding. The concept of sustainability in particular is dependent on mutual insight, because sustainability must be lived, it cannot be prescribed. For the social process of communication, it is therefore not sufficient to provide information. The information must be evaluated and turned into reality. Man finds himself in the dilemma of being flooded with information. There is an optimum opportunity to gain knowledge, but it must be examined with regard to its content, and this is almost impossible for an individual because of the volume and complexity of the data and the lack of yardsticks for evaluation. Such evaluation yardsticks must be drawn up in a dialogue and then be integrated in decision-making processes.

The willingness for dialogue and for being involved in processes to establish targets in society must be encouraged. Environmental education could contribute to this. In particular, it must extend the knowledge of systematic relationships,

particularly in the fields of ecology, economics, and society. An environmental education contributes to the formation of an awareness, which is a precondition for strengthening personal responsibility and motivation. These, in turn, form the basis for changes of attitude. Because Sustainable Development is a continuous process, it is essential that society is constantly willing to learn.

One factor concerning communication within the society which must not be ignored are the emotional aspects. These arise increasingly in discussion about the safety or risks of technology. Decisions, particularly by laypersons, are frequently not made on the basis of rational, well-founded considerations but are influenced by emotional factors, such as fear. Media reporting plays an important role in this. In general, emotions are very difficult to overcome with purely technical or scientific arguments, because there are two different planes here, the rational and the emotional, which inter-relate. In many cases, these planes collide irreconcilably with one another. Finding a solution is out of the question if emotions are not acknowledged as being arguments and given the same ranking as facts. Consequently, suitable forms of dialogue must be found which can bring about an agreement of opinion on the identification, evaluation and management of risks. Part of this dialogue is to discuss chances and risks and to weigh them against each other.

4.3. Risk/Chance Assessment

During the last two decades, there has been an increasing demand in the highly industrialized countries for safety and a declining willingness to take risks. Many people believe they are increasingly exposed to risks as a result of technical developments. There are a number of very different reasons for this feeling, depending on the individual's or society's mental approach, knowledge, and yardsticks. Undoubtedly, that the high present-day standard of living, with its high level of safety, and the fact that people can look beyond simply satisfying their basic needs and openly take in the side effects, too, play an important role. Other factors which have contributed to the intensification of discussions on the subject of risk include the improved possibilities for scientific research, e.g., environmental analysis, and the influence of the media.

Risk is a complex term with manifold problems concerning its comprehension. It is based on the word *risco*, which was common in Italy in the 1200s, when Venetian merchants used it to appraise the risk of loss of commercial fleets. In subsequent years, various disciplines (e.g., insurance mathematics, decision theory) have become involved with the phenomenon of risk, with the result that we have different definitions. Common to all of them is the fact that risk can be described as a concept for appraising an expected loss.

The term "risk" is linked to a whole chain of other terms: risk description/risk evaluation/risk comparison/risk perception/risk communication/risk management/risk acceptance. This shows that very different worlds of thinking come together in this term. Formulated simply, it covers the technical and scientific world of thinking, and the social and political world of thinking. The scope of competence for decision-making decreases in this order for the technical and scientific segment, but increases for the social and political segment. Figure 1 illustrates these relationships in schematic form: Risk description is predominantly a technical and scientific matter, while risk acceptance is primarily a social and political domain. This view should help to clear up the misunderstanding that a high level of expertise for describing risks necessarily leads to a high expertise for accepting risks. This does not apply conversely either.

Figure 1. Scope and competence for decision making

Deeper analysis of the subject of risk shows that only a holistic approach can lead to correct decisions. For the three segments of Sustainable Development, this means that ecologi-

cal, economic, and social risks must be weighed up against each other in order to proceed along the path of Sustainable Development. An approach to risk such as this can also be helpful in the context of conflict management, in which it has proved useful to examine conflict of facts/conflict of interest/conflict of convictions separately, and not to mix them unnecessarily.

Another source of misunderstanding is very often the opinion that a risk can be completely eliminated if the minimization measures go deep enough. A mathematical-formalistic approach shows, however, that risks, however comprehensive the countermeasures, can never be reduced to zero. This relationship can be described by a curve which approaches the baseline asymptotically but never reaches it (Fig. 2). In fact, the curve shows even more than this: measures to reduce a risk can themselves involve risks. Accordingly, there is a certain optimum of measures at which the risk is at a minimum. In other words, an excessive number of measures is just as harmful as too few. Dispensing completely with the benefits of something must also be viewed critically, because this approach can harbor new risks.

Figure 2. Relationship between risk and the measures taken to reduce it

There is an interesting analogy from the relationship between risk and the level of freedom in a society. The formal approach shows that plotting the level of freedom against the risk gives a curve with a distinct maximum (Fig. 3). This relationship must be interpreted such that only by accepting a certain level of risk can an optimum level of freedom be achieved. Too much risk is just as harmful for freedom as too little. The philosopher JASPERS described these often misunderstood circumstances as follows: "Human things do not permit any absolute safety. Freedom can only assert itself through freedom in risk. Anyone who wants absolute safety wants a lack of freedom and political death."

Figure 3. Relationship between risk and the level of freedom

The contemplation of freedom leads to a central, but frequently overlooked, aspect in the discussion of risk: risk infers not only an expectation of loss, but also an expectation of gain. Just as light and shade are connected with one another, so is risk connected with chance. Risk and chance cannot be separated from one another. Society, when considering questions of evaluation in technology, must be aware of this fact and its fate-related significance. For Sustainable Development, risk and chance provide the yardstick for measuring to what extent one of the three fields of ecology, economy, and social matters may be impaired. Risk/chance assessment is difficult, particularly because it poses the ethical question about criteria for whether a risk can be reasonably and responsibly accepted. The answer must be developed in social consensus with the aid of complex, cross-discipline discourse. One-sided approaches, which reveal only the chances or only the risks, are inappropriate. A differentiated view of the risks can also make an indispensable contribution to the concretization of the prevention principle.

4.4. Innovations

Concern about the future has also intensified the demand for appropriate, targeted innovations. They are seen as potential solvers of current problems, as a means to repair the past, and as the answer to ethical questions. It is also hoped

that they will have a long-term effect with regard to Sustainable Development.

Without innovations, human societies have no future. The emphasis on the importance of innovations is, however, not a modern idea. In the past, inventions were made that brought about profound changes in the social system and were connected not only with quantitative, but also with qualitative leaps. Printing, the railways , and fertilizers are just three examples.

In principle, the concept of innovation is very convincing. The actual meaning of the term innovation does, however, need evaluation. Innovation means renewal in the truest sense of the word, and, in the final analysis, creative destruction. In extreme cases, it can go as far as "revolution". In the technical world, a fundamental, far-reaching innovation is therefore often described as a "technical revolution". Innovation therefore means breaking with what currently exists and with traditions. It necessitates a willingness to make profound changes in structures and systems, and frequently unavoidably entails such changes. For humankind, this involves processes of rethinking and adjustment, which are not always desirable. They only receive approval if the change is accepted. This may be brought about either by insight or by suffering.

The call for innovations, however self-evident and logical it may be, must take several factors into account. First, innovations must not be confined to the field of research and development in the natural science segment. A demand for innovation also exists in other areas of science and in society and politics. Second, it is important to take a careful look at their interactions and consequences: Innovations are ambivalent, they conceal not only chances, but also risks. Third, creativity and hence innovation cannot be forced, it requires time and capital investment. Fourth, innovations must be accepted by society and be able to establish themselves in the marketplace. Fifth, innovations necessitate multidimensional interactions and a willingness of those involved to cooperate. Finally, they must not just be short-term solutions, they must take into account, in the long term and to an equal extent, the three fields of ecology, economy, and social matters.

It is important to look at this background when the chemical industry is called on to come up with innovations. That it should be involved is beyond doubt. Nevertheless, important preconditions for creativity include having sufficient space to move and adequate personal responsibility, which are oriented to the underlying social framework that has been established. Apart from the encouragement of innovative ideas, approaches already exist in the chemical industry for achieving Sustainable Development. They make no claim to finality but are parts of an iterative process.

5. Approaches of the Chemical Industry

Industry, and thus also the chemical industry, has adopted the idea of Sustainable Development. This was demonstrated, for example, by joining The Business Charter for Sustainable Development of the International Chamber of Commerce (ICC) [8], which was drawn up on the basis of the Brundtland Report in 1991 and contains 16 principles. Using natural resources sparingly and minimizing the impact of production and products on humans and the environment are two of the principles of the chemical industry. It has integrated Sustainable Development into its strategic targets and will contribute to the lengthy, continually advancing social process within the limits of its possibilities. It strives to intensify cooperation with politics and society.

5.1. Responsible Care

5.1.1. Basic Idea

The idea of Sustainable Development must be concretized by industry- and company-specific programmes and activities. An important contribution to this has come from the worldwide initiative of Responsible Care, which was developed by the chemical industry for the chemical industry (unilateral initiative) and is listed in Agenda 21 as a key step on the road to Sustainable Development. Responsible Care originated in the Canadian Chemical Producers Association. In 1984, this Association drew up guidelines containing the goal and the commitment to voluntarily and continuously improve services

in the fields of health care, safety, and environmental protection (HSE). Responsible Care thus goes beyond the legal requirements and is an initiative which relates to the future. It contains principles and guidelines for acting responsibly with regard to employees, neighbors, the public, and other branches of industry. In the meantime, the national associations of the chemical industry throughout the world have joined the initiative and formulated or adapted their guidelines. For the member companies of the associations, these guidelines are binding.

The concept of Responsible Care contains ten directives [9], which basically correspond to the demands laid down in The Business Charter for Sustainable Development (ICC) [8]. Among the key points in the initiative are the setting up of a suitable management system and the greater integration of individual employees. Their personal responsibility for environmental protection and safety is underlined, and they are called on to strengthen and sharpen their environmental awareness and personal initiative. They should act in line with corporate environmental protection and safety objectives, and supplement them with their own ideas. Apart from the guidelines, the Responsible Care concept also includes management practice codes for the fields of product stewardship, plant safety and hazard prevention, occupational safety, environmental protection, transport safety, and dialogue. The basic principles for these areas are described in Germany, for example, in guidelines issued by the national Chemical Industry Association (VCI) and many member companies [9], [10]. The task of environment management and of every individual is basically to put the guidelines into practice.

To effectively implement the basic aims of Responsible Care, a regular check must be made as to whether the self-imposed targets have been achieved by the measures taken. The aim of this target/actual comparison is to instigate any corrections which may be needed. It is, however, also the expression of a willingness to learn, which is necessary for a lasting goal (see Section 4.2). The workforce and the general public should be regularly informed about the goals and the results. For this purpose, the goals must as far as possible be measurable and understandable.

In summary, the three major elements of Responsible Care are proactive action, participation, and prevention. With Responsible Care, the ethical component has been incorporated into industrial programming. Responsible Care can be seen as a serious endeavour to take up Jonas' responsibility concept (see Chap. 3), and to assume responsibility in the sense of responsibility ethics with its own code of conduct.

The following section examine various examples from individual segments to demonstrate the practical implementation of the Responsible Care idea.

5.1.2. Management Systems

When setting up management systems, the aim is to find forms of organization which point the way to continuous improvement and set and perpetuate targets with personal responsibility. In clearly formal terms, it begins with taking stock of all the data of relevance to environmental protection and safety. From this, targets are set and announced, then measures are drawn up to implement them. After a fixed period of time, a comparison is made between the target and what has actually been achieved, for example in the form of an audit, either performed in-house or by external experts. This may result either in corrections to the original course or the setting of new targets. The formal procedures of the management system, information flows and responsibilities are compiled in a manual.

The preconditions for the success of management systems are the active involvement, motivation and creativity of the employees who are to achieve the improvements. Internal and external communication therefore plays a key role (see Section 5.1.4).

5.1.3. Production-Integrated Environmental Protection

The target aspects of Sustainable Development, namely to conserve resources and reduce the impact on the water, soil, and air, are identical to those of production-integrated environmental protection. Being a preventive form of environmental protection, it aims to use raw materials and energy sparingly, and to avoid, reduce, or recycle emissions of solid waste, wastewater, and waste air. Avoidance has the highest

priority, and disposal the lowest. Production-integrated environmental protection thus contrasts starkly with end-of-pipe environmental protection, which comes at the end of the production chain with subsequent waste disposal. Although this latter kind of industrial environmental protection was very successful in the 1960s and 1970s and made a major contribution to improving the environmental situation, it is nevertheless a kind of repair job, which, for its part, consumes energy and raw materials and generates considerable costs. Over the last few years, a structural change in environmental protection has taken place in the chemical industry away from disposal to preventive measures [11]. Here, the emphasis is quite clearly on production-integrated environmental protection.

Established production processes are being overhauled and new processes developed in accordance with the set targets of avoidance, reduction and recycling. The basic principle is nothing new in the chemical industry: the concept of coupled production – production in which byproducts from a process constitute the starting materials for new products – is extremely important for the chemical industry and has been practised for a long time. The environmental aspect has gradually been added in recent years. The search is for processes which utilize raw materials with a maximum efficiency and have as little impact as possible on the air, water, and soil from the very beginning. This can be achieved in various ways, including, for example, intelligent, innovative procedures in combination with optimum control techniques, the development of higher performance catalysts, and the setting up of closed material circuits.

Every modification to a process is a one-off situation which costs a lot of time and money and which must, in principle, answer questions concerning technical feasibility, economic viability, and ecological benefit. Interdisciplinary cooperation is needed to look at the relevant process from various points of view. Basically, modifications to processes should not be made merely under the aspect of ecology, but must also take other circumstances into account, for example, safety, material, energy, and economic factors. Wherever possible, these must be weighed up against each other. Semi-optimized, short-term solutions frequently create more problems in the long term and do not bring any real increase in efficiency.

Production-integrated environmental protection has already provided considerable impetus in the chemical industry in the past few years, and can look back on a number of successes [9], [11] (see also → Production-Integrated Environmental Protection). It offers chances not only for ecological improvements, but also for enhancing quality and saving costs. Because of these clear advantages over end-of-pipe environmental protection, production-integrated environmental protection will make an important contribution to safeguarding the future. In the context of Responsible Care, it will be consistently pursued with a high level of personal responsibility.

5.1.4. Product Stewardship

The integrated, preventive approach for protecting the environment and humankind also applies to the products of the chemical industry [9], [12], [13]. The aim is minimize the risks emanating from products with respect to their their production, packaging, marketing, handling, use, and disposal. Product stewardship means taking account of the health, safety, and environmental aspects of a product during its entire life cycle. It begins in the field of research and development, continues through production, storage, and marketing, but does not end when the product is used. It also considers its final destination, and includes recycling and disposal. It thus requires cooperation, not only from companies in the chemical industry, contractors and clients, but also from all other parties involved in the chain, starting with procurement of the raw materials and ending with the product's final disposal. This interindustry, intercompany communication allows a comprehensive examination and evaluation of the product, and provides an opportunity to search out and implement potential ecological improvements. Ultimately, it should lead to an improvement in product design.

Despite the overlap aspect, the individual companies and branches of industry must develop their own programmes and incorporate them into their management systems. Product stewardship is an important part of the Responsible Care initiative.

An efficient concept for product stewardship also encompasses risk management, which includes risk/chance assessment. Within this context, it is important to start with comprehensive knowledge of the ecological and toxicological properties and the effects of a substance in order to be able to describe its hazard potential. The actual hazard and the probability of its occurring, that is, the risk, can only be assessed after an analysis of its exposure. Here, an examination is made as to whether and to what extent ecosystems or living creatures are actually exposed to the substance. This is followed by an evaluation. This process must be carried out very carefully, and the chances and risks must be specifically weighed against each other. The process of actually passing judgement is best carried out at the interdisciplinary level. The result is a risk assessment which takes appropriate account of ecological and economic aspects. The next step after the evaluation phase is to deal with concepts and strategies to draw up measures through which risks can be compensated.

The range of tests and evaluations reveals very comprehensive, complex work. Scientific method development is being intensively pursued. Targeted communication between employees, customers, users, and contractors necessitates comprehensive information on the health, environment, and safety aspects of a product. The chemical industry is intensively involved not only in this, but also in the further development of the integrated concept of product stewardship.

5.1.5. Dialogue

To implement the idea of Sustainable Development, dialogue in society as a whole is absolutely essential (see Section 4.2). The chemical industry participates in this to a very high degree [9]. Firstly, it issues a wide variety of written and electronic information, for example, environmental reports, which provide information on recent achievements and developments and on the company's goals, and those of the chemical industry as a whole, in the context of Responsible Care [14].

Secondly, the chemical industry greatly encourages personal dialogue. This extends beyond the traditional exchange of know how and experience among experts, and now covers all sections of society. After all, only through communication between those affected and those involved is it possible to move closer together and, in particular, understand each other. This is an essential requirement in finding a consensus of opinion in situations of conflict. One important point here is that the doubts and misgivings of the population are taken seriously and that they are included in the planning. To improve communication, the chemical industry, for its part, stages a wide variety of events on a general or scientific basis (e.g., press conferences, open days, guided tours). Exhibition and communication centers offer on-site forums for discussion [15], and the Internet also encourages dialogue. Apart from this, the chemical industry actively participates in a wide range of discussions with the general public and with political leaders.

The chemical industry attaches major importance to internal dialogue. Staff motivation, which is so important for the Responsible Care initiative, is based on a consistent supply of information. For this purpose, the chemical industry has set up compulsory, target group-oriented training programmes for the workforce [16]. The aim is to further the knowledge of environmental protection and safety with relevance to the respective plant or department, and also to see it in a company-wide context. Another aim is to strengthen the feeling of personal responsibility. The system is supplemented by in-house newspapers and other written documentation.

5.2. Environmental Agreements

The chemical industry is prepared, together with politicians, to draw up environmental targets and solve recognized problems on its own responsibility and on the basis of agreements. A number of such agreements have been reached in the past few years in the fields of environment, safety, health, consumer protection and energy. These are either bilateral agreements between the industry and the authorities, or unilateral initiatives. Examples relating to the German chemical industry include the voluntary existing chemicals programme, the agreement to halt CFC production, the agreement with the city of Rotterdam to reduce contamination of harbor sludge, and the self-imposed commitment to lower CO_2

emissions. In practice, there are many possibilities for reaching voluntary agreements. They differ in their detail.

As a rule, the agreements are reached for the branches of industry by the relevant associations. In individual cases, the companies can also enter into agreements themselves and thus join in directly. In any case, each agreement has to be worked out individually and necessitates comprehensive dialogue. The actual route to achieving the target is largely left to the companies or branches of industry. Any scope for adjustment and cost benefits may be utilised. In the case of long-term targets, it is advisable to include quantified intermediate targets, in order to assess at a relatively early stage whether the measures taken so far are sufficient for reaching the target or whether corrections have to be made. The agreements include an obligation by the chemical industry to exert a vigorous influence to make sure the agreed aims are reached.

Complying with the agreements is important for the chemical industry. First of all, it offers the security of long-term planning and investment projects. Secondly, the agreements can lead both to ecological and to economic advantages and, in this respect, they also act as an instrument to stimulate the willingness and ability to innovate.

Ψ soil water potential

1. Ecology and Environment

1.1. Humans and Environment

In the course of their evolution, humans have exerted an ever-increasing influence on the terrestrial and aquatic environments that ensured their livelihood. In early Paleolithic times, *Homo erectus* was dispersed over large geographical ranges of the Old World continents and had already attempted to circumvent environmental limitations, via culture, in expressing dietary preferences different from the youngest australopithecines and in colonizing both drier and colder environments. Because of their food preferences, these hunters and gatherers probably required larger territories and thus comparatively few Acheuleans could be supported in any one area; consequently, mobility and the periodicity of seasonal activities were considerable [1], [81]. The sites occupied indicate a preference for open, grassy environments with large herds of gregarious herbivores, which means that human influence on ecosystems was by no means different from that of hunting or gathering animals.

Things changed drastically during the tenth millennium B.C., when the first agricultural societies arose. The new subsistence system, based on crop planting, livestock raising, and permanent settlements, had been developed to the point that long-term population increases became possible. Significant ecosystem changes, often associated with disturbances of the hydrological cycle and soil erosion [82], resulted when native floras and faunas began to be replaced by domesticated stock and cultigens. Thus, not only were the largely prevailing agrarian and woodland ecosystems profoundly changed in species composition, but natural recycling processes also constantly lost importance.

In the present millennium, characterized by an unprecedented population increase in the last two centuries, the formerly "isolating" woodlands or uncultivated areas around the agrarian ecosystems and settlements have been constantly reduced, which means that the ecological buffering capacity of these nonagrarian areas, which had such an important role in the intricate ecosystem interplay of the past, no longer exists in densely populated regions of the world. Consequently, both aquatic and terrestrial types of ecosystems are now open to human impact on the regional and continental levels, and present-day analytical knowledge provides ample evidence that even the most remote areas on earth bear more or less marked imprints of human activity.

Among them, chemical imprints have attracted particular attention, because their importance has grown since the middle of the last century with ever-increasing speed, and the development is not likely to change in principle, albeit sectoral differentiations are evident. A comparison of high-volume chemicals illustrates for the United States that petroleum derivatives represent 10 % of the total number of entries in the inventories, but account for 55 % of the total production, whereas inorganics represent both 12 % of the materials and 12 % of the production. Another 6.9 % of the production is due to materials

Table 1. Estimated global release of organic reference chemicals in 10^3 t/a (after [84])

1,2,3-Trichlorobenzene	0.09	1,2-Dichloropropane	15
1,3,5-Trichlorobenzene	0.09	Diethyl phthalate	23.1

γ-HCH (lindane)	14.1		

that are residues from the processing of ferrous metals. Saturated hydrocarbons are responsible for 6.7 %. Well-defined organic substances are the most numerous, and cause major concern in testing, because they account for about 34 % of the inventory sample, but only 6 % of the total production. Polymers and plastics represent 24 % of the number of materials and 3 % of the total production [83]. Table 1 provides insight into the estimated global release of organic reference chemicals. The figures listed indicate that humans, owing to the accelerated growth of the chemical industry since the 1950s, produce and use many synthetic compounds that, in localized exposure at least, no longer appear to be negligible in comparison to natural fluxes and concentrations. Thus, the ecological role of humans has changed profoundly in little more than a century of their long cultural history, because they are now capable of and responsible for introducing new substances or increasing the concentration of natural ones in the environment to an extent unthought of in the past [2].

Because the products of the chemical industry are also a most essential part of both our economic and our social life, governments and industry alike have become increasingly concerned about the potential, unintended consequences that the use of man-made chemicals could have on both human health and the environment. Therefore, a number of key chemical-producing countries have passed, or are enacting, general substance control legislation (→ Legal Aspects, Chap. 2., → Legal Aspects, Chap. 6., → Legal Aspects, Chap. 7.). Common to all these legal instruments is the preventive aspect (i.e., the notification of chemicals prior to marketing), which entails the presentation of data derived from laboratory investigations together with additional information to permit the evaluation of potential hazards.

1.2. Scope of Ecology and Ecotoxicology

Environments are highly complex systems whose evolution is determined by complicated networks of positive and negative feedback loops. Human interference, particularly when inadvertent, is therefore reflected in an ever-

increasing number of environmental problems that cause major concern in today's societies. To better understand and resolve these problems, knowledge of the basic earth and life sciences unified under a comprehensive ecological perspective is essential, and a consideration of the bewildering number of interrelationships from a generalized system point of view appears indicated.

Ecological thinking began to emerge in the 17th and 18th centuries [3], while the very term "ecology" as derived from the Greek *oikos* (home) was coined and introduced into biological terminology by HAECKEL [4]. Paraphrasing HAECKEL, ecology can be defined as the scientific study of the interactions between organisms and their environment or, more informatively: "Ecology is the scientific study of the interactions that determine the distribution and abundance of organisms" [5]. The environment of an organism consists of all those physical and chemical (abiotic) or biotic (other organisms) factors and phenomena outside the organism that influence it.

At the *level of the organism*, ecology deals with how individuals interact with their biotic and abiotic environments (autecology). At the *population level*, ecology determines the presence or absence of particular species, their abundance or rarity, and trends and fluctuations in their numbers (demecology). Two approaches can be distinguished at this level: one deals first with the attributes of individual organisms and then considers the way in which they combine to define the characteristics of the population. The other deals directly with the characteristics of populations and relates these to relevant aspects of the environment. *Community ecology* deals with the structure of communities and with the pathways and fluxes of energy, water, nutrients, and other chemicals through them. This implies adequate consideration of human influence on nature (e.g., pollution and global warming).

Since ecology must deal explicitly with these three levels of the biological hierarchy and the overwhelming multitude of interactions between organisms and their physical, chemical, and biological environments, it is particularly subtle and complex. Yet ecology also has the distinction of being confronted with uniqueness in a very peculiar way: it must consider millions of different species, each composed of frequently countless numbers of genetically distinct individuals, all living and interacting in a highly varied and ever-changing world. Thus, "the beauty of ecology is that it challenges us to develop an understanding of very basic and apparent problems, in a way that recognizes the uniqueness and complexity of all aspects of nature but seeks patterns and predictions within this complexity rather than being swamped by it" [6].

Ecology of such a comprehensive scope cannot be an easy science but must be a complex interdisciplinary structure grouping several dozens of sciences on the basis of a hierarchically structured system of hypotheses. For instance, one of the major present-day ecological research schemes, the long-term ecosystem research project in the Bornhöved Lake District (Schleswig-Holstein) comprises no less than 25 disciplines, ranging from mathematics to social sciences, around a nucleus of physical, chemical, biological, and earth sciences [85].

Ecotoxicology may be defined as "a science which is concerned with the toxic effects of chemicals and physical agents on living organisms, especially on populations and communities within defined ecosystems; it includes the transfer pathways of those agents and their interactions with the environment" [7]. In formal analogy with the objectives of classical toxicology, which has evolved as an aut- or demecologically oriented discipline, ecotoxicology aims at defining toxic effects in terms of reactions of ecosystems or representative compartments of such systems. In view of the complicated structure of ecosystems and their tremendous variability in time and space, however, particular problems arise. While many experimental approaches exist to predict the hazards of drugs, food additives, and contaminants for humans (→ Toxicology, Chap. 3., → Toxicology, Chap. 5.), which are based on extrapolation from animal or other data, the analogous ecotoxicological procedures are much more complicated and hitherto far less satisfactory [8].

The very crux of the ecotoxicological extrapolation problem is the difficulty that an eventual decision-making process will lead to either "false negatives or false positives" [86]. In this connection, a false negative implies that a chemical that appears acceptable on the basis of laboratory data may cause considerable damage in

practical circumstances. If, for instance, the prediction of possible environmental exposure levels on the basis of standardized laboratory tests turns out to underestimate the actual levels occurring in "real-world" environments, populations of certain species will be much more at risk than expected. Thus, species with mono- or oligomaniacal feeding behaviors (i.e., food specialists), run a much higher risk of bioaccumulation effects if specific chemicals are applied against their favorite or only prey than less specialized predators.

In contrast, the false positive involves rejection of chemicals because laboratory tests indicate intolerable hazards for the environment, while in fact such undesirable effects are not likely to occur. Pesticides may be labeled toxic to fish on the basis of standardized laboratory trials, although this does not necessarily imply that they will always cause mortality in fish when applied in, or in the immediate neighborhood of, their natural aquatic habitat. The framework of tsetse fly control in West Africa amply demonstrated that the potentially fish-toxic insecticides endosulfan and deltamethrin could actually be used without having any noticeable effects on fish [87]. The effective dose rate for killing tsetse flies was minimized by careful selection of the insecticide formulation on the one hand and application methods on the other.

Thus, the hazards of pesticides usually depend on such factors as the amount applied, formulation, methods and times of application, and intensity of use, which are – in their extremely variable specific combinations – virtually impossible to simulate. Attempts must be made, therefore, to consider the ecological characteristics of target areas as well as possible nontarget effects in connection with the use pattern envisaged in order to avoid unrealistic predictions. A compound that appears unacceptable in a certain application in one place need not be so in another. Hence, basic physical – chemical data such as those described in the *Collection of Minimum Pre-Marketing Sets of Data* of the OECD Working Group on Exposure Analysis [88] have to be matched to data on the relevant properties of typified environments into which the compounds are ultimately released. From this particular perspective, the essential structural and dynamic characteristics of both chemicals and ecosystems that are relevant to ecotoxicology are described in the following chapters.

2. Principles of Ecology and Environmental Chemistry

2.1. Structure and Dynamics of Terrestrial Ecological Systems

2.1.1. Structure of Communities and Ecosystems

In a classic paper, TANSLEY [89] defined the term *ecosystem* as "... the whole *system* (in the sense of physics), including not only the organism-complex, but also the whole complex of physical factors forming what we call the environment of the biome – the habitat factors in the widest sense. Though the organisms may claim our primary interest, when we are trying to think fundamentally we cannot separate them from their special environment, with which they form one physical system. It is the systems so formed which, from the point of view of the ecologist, are the basic units of nature on the face of the earth .... These ecosystems, as we may call them, are of the most various kinds and sizes. They form one category of the multitudinous physical systems of the universe which range from the universe as a whole down to the atom."

From the definition of an ecosystem as an arbitrary unit with respect to both its spatial extent and the phenomena considered, ecosystems are often portrayed as food webs or graphs in which "all" the trophic relations between component species are given [9], [10], [90]. Species can also be grouped into a hierarchy of trophic levels or size spectra [11], [91], [92], which facilitates an understanding of the flows of energy and matter through a community and underscores biological differences in interactions within and between levels. Because of the impacts of pollution and environmental change on the living world [2], the concept of stability has also been germane to the argument of how best to depict ecosystems (Section 2.3.1).

Figure 1 illustrates that an ecosystem can be viewed as a composite of the lower levels of organization (i.e., communities, populations, and individuals). Coexisting individuals of a single species possess characteristics such as density,

sex ratio, age – class structure, rates of natality and mortality, and immigration or emigration that are unique to *populations*. The *community* is an assemblage of species populations that occur together in space and time.

In proceeding from the level of physiological and behavioral ecology – dealing primarily with individuals – to the ecology of populations and communities, collective properties such as species diversity, community biomass, and productivity can be identified. Organisms of the same or different species interact with each other in highly diversified processes of mutualism, parasitism, predation, and physical or chemical competition. Thus, the nature of a higher organizational level is obviously more than just the sum of its constituent parts; it is their sum plus the interactions among them. Thus, *emergent properties* appear only when increased complexity (i.e., different levels of organizational structure) is the focus of attention. A primary aim of community and ecosystem ecology is to determine whether repeating patterns in collective and emergent properties exist, even when the differences in the particular species that happen to be assembled together are great. Discussions need not be segregated as ecosystem rather than community topics, since these phenomena depend explicitly on fluxes between living and nonliving components of ecosystems. Thus, for instance, detailed knowledge of the role that communities play in biogeochemical cycling is essential for understanding and adequately combating the effects of acid rain or the increasing levels of atmospheric CO_2 on forests, fields, greenlands, streams, lakes, and other communities.

2.1.1.1. Description of Community Structure

The apparently simplest way to characterize a community is to list its species, but in practice this may become surprisingly difficult, because of taxonomic problems and because usually only a subsample of the organisms in an area can be counted. Thus, the *species richness* of different communities can properly be compared only if investigations are based on the same sample sizes in terms of the area of habitat studied, the time devoted to sampling, or the number of individuals or modules included in the samples. Statistics in general, and geostatistics in particular, are essential to ensure valid sampling (see, e.g., [12], [13], [93]).

The simplest measures that take into account both species richness and abundance or biomass patterns are diversity indices. As examples, the Simpson, McIntosh, and Shannon diversity indices are given:

The Simpson index [94] is

$$D=\left(\sum_{i=1}^{S} p_i\right)^{-1} \tag{1}$$

where D is the diversity index, S the total number of species in the community, and p_i is the proportion of individuals or biomass that it contributes to the total in the sample. An important further specification is expressed by the term evenness (or equitability, E), i.e., the proportion of the maximum possible value D would assume if individuals were completely evenly distributed among species:

$$E=D\cdot D_{\max}^{-1} \tag{2}$$

Evenness assumes a value between 0 and 1.

The McIntosh [95] index is given as

$$D=\left[N-\left(\sum_{i=1}^{n} n_i^2\right)^{\frac{1}{2}}\right]\cdot\left(N-N^{\frac{1}{2}}\right)^{-1} \tag{3}$$

where N is the total number of individuals in the community and n is the number of individuals per species. In Section 2.3.3, the McIntosh index is used in the framework of stability-oriented analyses of biodiversity.

Shannon's diversity index H [96] again depends on an array of p values; thus,

$$H=-\sum p_i \ln p_i \tag{4}$$

and

$$E=H\cdot H_{\max}^{-1}=H\,(\ln S)^{-1} \tag{5}$$

Since an infinite number of logarithmic systems exist, different authors use other logarithms, in particular those with bases 2 and 10, which should be specified when calculating H.

Figure 1. Graph model of an ecosystem (after [90], modified)

Figure 2. Rank – abundance histograms of epigeic spider communities from various ecosystems of the Bornhöved Lake District (Schleswig-Holstein) (after [85])

Rank – abundance diagrams provide a more complete picture of the distribution of species abundances in a community since they make use of the full array of p_i values by plotting p_i against rank. A rank – abundance diagram can be drawn for the number of individuals, for the area of ground covered by sessile species, or for the biomass contributed to a community by various species (see Fig. 2).

Other classical statistical techniques to reduce the subjectivity of community description are ordination and classification.

Ordination organizes communities on a graph so that those that are most similar in both species composition and relative abundance appear closest together. To this end, the axes of the graph are derived mathematically solely from the species composition of the various stands. Interpretation of the resultant patterns in terms of environmental variables is the second step, in which the scatter of points in the ordination is analyzed to see if the axes correspond to ecologically relevant gradients. Since the latter can be brought about by a host of interactions and a priori determination of the important ones is not possible, the same critical remarks relative to gradient analysis (see below) apply to the interpretation of ordination diagrams.

Classification, in a sense opposed to ordination, produces groups of related communities by a process conceptually related to taxonomic classification. Communities with similar species compositions are grouped together in subsets, and similar subsets may be further combined in a sequential manner by means of clustering algorithms [14], [97]. Figure 3 provides an illustration of such a community analysis (Fig. 3 A) and classification (Fig. 3 B), in which the primary characterization of the individual phytosociological units and the related Collembola faunas was effectuated by means of Renkonen indices.

Gradient analysis and canonical correspondence analysis are uni- and multivariate approaches to detect patterns in communities. In the first case, the investigator searches (sometimes with a considerable amount of subjectivity) for some feature of the environment that appears to matter to the organism. Then, data about the species concerned are organized along a gradient of that factor, which is not necessarily a priori the most appropriate factor. The fact that individual species from a community can be arranged in a sequence along a gradient may imply only that the factor chosen is loosely correlated with whatever really matters in the lives of the species considered. Thus, gradient analysis is a minor step on the way to the objective description of communities.

Canonical Correspondence Analysis. Much better suited to unravel the intricate interplay of environmental factors and to define their relative importance more precisely are multivariate methods (for a comparative analysis, see [98]). The canonical correspondence analysis [99] compares optimum and pessimum curves of species with Gaussian distributions on the basis of multivariate data obtained in the field. Figure 4 illustrates the results of such an analysis for the Collembola fauna of several stands of the Bornhöved Lake District (Schleswig-Holstein). In analogy to biplot analysis described below, in Figure 4 the orthogonal projection of the points marking species on the various vectors (environmental factors) defines the relative importance of these factors for the distribution of the Collembola species explored.

Biplot analysis [100], [101] permits analysis of the inherent structure of comprehensive geographic data matrices, representing, for instance, organisms (O_n) in relation to metrically defined site factors (F_m).

$$[\boldsymbol{M}\,(O_n, F_m)]_{1<n,m} \tag{6}$$

Such an $n \times m$ matrix is equivalent to a cluster in m-dimensional space, where m is the number of factors as related to n organisms considered. This equivalence means that any matrix with $n \times m$ elements may be represented by one vector for a row and another vector for each column such that the elements of the matrix are the inner products of the vectors. When the matrix is of rank 2, or if a higher-rank matrix can be closely approximated by a matrix of this rank by using singular-value decomposition procedures, the vectors may be plotted and the resulting matrix representation (i.e., the biplot), inspected visually. Thus, a biplot not only permits viewing the individual data and their differences, but

Figure 3. Cluster analysis of plant communities and related Collembola faunas in the Bornhöved Lake District (after [85]) A) Group analysis; B) Formation of subsets and clusters

Figure 4. Canonical correspondence analysis of the Collembola faunas of different sites in the Bornhöved Lake District (after [85])
Species: *Brachystomella parvulu, Cryptopygus thermophilus, Dicyrtoma fusca, Dicyrtoma minuta, Dicyrtoma saundersi, Entomobrya corticalis, Entomobrya muscorum, Entomobrya nivalis, Folsomia listeri, Folsomia quadrioculata, Frisea mirabilis, Hypogastrura armata, Hypogastrura denticulata, Isotoma notabilis, Isotoma viridis, Isotomiella minor, Isotomurus palustris, Lepidocyrtes cyaneus, Lepidocyrtes lanuginosus, Odontella lamellata, Onychiurus pseudovanderdrifti, Orchesella cincta, Orchesella flavescens, Pseudachorutes dubius, Pseudachorutes subcrassus, Pseudosinella alba, Sminthurus fuscus, Sminthurus lubbocki, Tomocerus flavescens, Tomocerus minor, Tullbergia callipygos, Tullbergia krausbaueri, Xenylla grisea*

further allows scanning the standardized differences between units and inspecting variances, covariances, and correlations of the variables.

Chi-Square Automatic Interaction Detection. In addition to the above analytical procedures for metric data, chi-square automatic interaction detection (CHAID) is a hierarchically disaggregative classification procedure for nominal and ordinal data [98]. As a multivariable procedure, CHAID subdivides the base set of data automatically in relation to χ^2 values and significance levels into exhaustive subsets. Because of mathematical advantages and the easy interpretability of the resultant dendrogram presentation of data, it has found wide application in forest dieback studies in Germany [102], [103]. Figure 5 illustrates the results of a comprehensive CHAID analysis of environmental factors at 895 sites in North Rhine-Westphalia that proved to be of decisive importance for forest damage.

2.1.1.2. Successions

The relative importance in the community of many organisms (particularly those with relatively short lifetimes) changes with time of year because of seasonal change. In addition, interannual variations in the abundance of species oc-

$p < 0.01$; C = Normed contingency coefficient; PR = Productivity rate; x = No differential information

Figure 5. CHAID dendrogram of site factors controlling forest damage in North Rhine-Westphalia (after [103])
$p < 0.01$; C = Normed contingency coefficient; PR = Productivity rate; x = No differential information

cur because individual populations respond to a multitude of environmental factors that influence their reproduction and survival rates. On still higher time scales, different processes of succession occur, which may be defined "as the nonseasonal, directional, and continuous pattern of colonization and extinction on a site by species populations" [6]. On any time scale, successions are of particular ecotoxicological interest since the varying communities normally have different stability, resilience, and consequently sensitivity properties.

The underlying mechanisms of such serial replacements may be quite different. *Degradative successions* usually occur over a relatively short time scale of months or years [104]. Any packet of dead organic matter – for example, litter, the body of an animal, or a fecal deposit – is exploited by microorganisms and detritivores. Normally different species invade and disappear in turn, as degradation of the organic matter uses up part of the resources and makes others available. Ultimately, degradative successions come to an end because the resource is completely metabolized and (partly) mineralized [15], [16].

In addition, autogenic and allogenic successions can be distinguished. *Allogenic successions* occur as a result of changing external environmental conditions (e.g., changes in habitat quality due to erosion or deposition, modifications of soil pH). *Autogenic successions* usually occur on newly exposed landforms, and one of the principal forces driving this type of serial replacement is the change in soil conditions caused by the early colonists. These may alter the availability of resources (e.g., nutrients) in a habitat, in such a way that the entry of new species is facilitated. The process of *facilitation* [105] may be particularly important in primary successions where conditions are initially severe [e.g., on till laid bare after the retreat of a glacier or inland ice (see Section 2.3.7)]. Another mechanism underlying autogenic succession is inhibition – specific modification of the environment by early species that makes it less suitable for recruitment of "late-successional" species.

Connell and Slatyer [105] proposed three models whose fundamental characteristics are summarized in Figure 6. Hemprich [106] modeled the changes in community composition on the basis of comparative phytosociological analyses in the Bornhöved Lakes area. Figure 7 is an example of successions in grassland communities that typically take from several decades to hundreds of years to run their course.

2.1.1.3. Patch Dynamics

Disturbances that open up gaps in woods may be caused by the death of a tree, high winds, lightning, animals, or lumberjacks. Perturbations in grassland communities may be due to frost, to grazing or burrowing animals, and to the feet and dung of grazers. The formation of such gaps of highly variable size is of importance to sensitive or sedentary species with a requirement for open space, whereas it matters comparatively little in the lives of mobile animals for whom space is not a limiting factor.

Viewing the evolution of communities or succession from such a "patch-dynamics" point of view leads to an important class of models consisting of a number of cells that are colonized at random by individuals of different species. Although species interactions within cells proceed according to Lotka – Volterra principles [107], the stochastically cellular structure of the community and the manifold opportunities in each generation for migration between cells allow species-rich communities to evolve and persist. Thus, patch-dynamics models are much more realistic than equilibrium models with resource partitioning and niche differentiation (e.g., [108–110]) or nonequilibrium models incorporating temporal variation in conditions (e.g., [111]), which both deal with closed systems. Patch-dynamics models including competitive interactions and dispersal are of particular interest in an ecotoxicological context. Dhôte and Hollier [112] considered the dynamics of forest stands from two complementary points of view, namely, their intrinsic biological behavior and their management. This involves explicit consideration of different spatial and temporal scales, levels of organization, and model aggregation. Yodzis [113] distinguished two different types of community organization depending on the type of competition between component species. The case in which some species are competitively superior is called "dominance controlled", while the other with

Figure 6. Essential mechanisms underlying terrestrial plant successions (after [105])

all species having similar competitive abilities is "founder controlled."

Dominance-Controlled Communities. In dominance-controlled communities, disturbances that open up gaps lead to relatively predictable species sequences, where early species are good colonizers and fast growers, whereas later species can tolerate lower resource levels and grow in the presence of early species, eventually outcompeting them. Thus, the community regains the climax stage when the most efficient competitors oust their neighbors. Disturbances may be synchronized, or phased, over extensive areas (e.g., bush or forest fires). Other disturbances are much smaller and thus produce a mosaic of patches, particularly if these disturbances are unphased. The resultant climactic macrosystem has a much higher species diversity than an extensive area undisturbed for a very long period and occupied by just a few dominant species.

Figure 7. Successions in grassland communities of the Bornhöved Lake District (after [106], modified)
E = Eutrophication; P = Pasture; O = Overgrazing; H = Hay harvest; F = Fallow

Gap size and structure (defined in terms of relief, soil, climate, etc.) are important factors of community structure because they induce contrasting mechanisms of recolonization. The central parts of very large gaps are likely to be colonized by species propagules that can travel greater distances, whereas the smallest gaps may be filled by simple lateral movements of individuals around the periphery. Regrowth results from seeds, plants established prior to disturbance, and lateral growth of branches from surrounding trees. Nearer ground level, colonization is frequently due to saplings that were already present but suppressed [114]. Also, animals can be overrepresented in gaps, as LEVEY [115] has shown in a study of tropical rain forest in Costa Rica. Here, nectarivorous and frugivorous birds were much more abundant in treefall gaps where understory plants tend to produce distinctly more fruit over longer periods than conspecies fruiting under an undisturbed canopy.

Founder-Controlled Communities. Whereas in dominance-controlled communities colonizing ability and competitive status are inversely related, founder-controlled communities are characterized by species that are both good colonists and essentially equal competitors. If a large number of species nearly equivalent in their capacity to invade gaps, and equally tolerant of the abiotic conditions, can "defend" the gaps against all comers, then the probability of competitive exclusion is much reduced in communities where gaps open continually and randomly. On each occasion an

organism dies, a gap is reopened for invasion. Thus, all conceivable replacements are possible and biodiversity will be maintained at a high level. An additional factor is the unpredictability of neighboring individuals in space and time, which contributes to reducing the likelihood of competitive exclusion of one species by another in the cause of succession. In any case, however, numerous feedback relationships exist between local and regional successional dynamics and the energy and water balances of the ecosystems affected.

2.1.2. Water Balance of Ecosystems

A number of models for plant – environment interactions, and particularly for the utilization of water and energy by plants, have been developed since the 1950s. Several of these attempt to understand plant growth and water use as related to specific physiological and environmental parameters [116], [117]. These models, however, cannot be applied to situations for which few data are available unless a number of simplifying assumptions are used. On the regional and geographical levels, other models of a predominantly qualitative character have been suggested [118–120]. As a consequence of this dichotomous development, attempts have been made to unify these two approaches with a view to simplifying the comprehensive models, so as to make them applicable to regional use in areas with limited data, without introducing misleading oversimplifications.

Examples of soil – water balance studies that appear to partly fill in this middle ground are those of Fuchs and Stanhill [121], Slatyer [122], Benecke and Van Der Ploeg [123].

The soil – water balance equation is generally written in the form:

$$P - R_S - (GWR + TF) - ET + \Delta\,(SM + SW + GW) = 0 \tag{7}$$

where P denotes precipitation, R_S the surface runoff, GWR the groundwater runoff, TF the throughflow, ET evapotranspiration, SM soil moisture, SW the perched water (above a compact horizon), and GW groundwater. For the sake of greater convenience, $(GWR + TF)$ is termed deep drainage, and $\Delta\,(SM + SW + GW)$ is the change in soil water storage (initial minus final) during the period and for the depth of measurement. For a number of cases, deep drainage may be adequately defined as the amount of water passing beyond the root zone or, for experimental purposes, as the amount passing below the lowest point of measurement. All symbols have dimensions of length, for example, millimeters. Equation (7) can be written more specifically as

$$\int_{t_1}^{t_2} [(P - R_S) - (ET) - v_z]\,\mathrm{d}t = \int_{t_1}^{t_2}\int_{0}^{z} \frac{\partial\,(SM)}{\partial t}\,\mathrm{d}z\mathrm{d}t \tag{8}$$

where $(t_2 - t_1)$ is the time interval over which the measurements are made (s), z is the depth to the lowest point of measurement (cm), v_z is the net downward flux of water at depth z (cm/s), and SM is the soil moisture, i.e., the volumetric soil water content (cm^3 of water per cm^3 of soil). P, R_S, and ET are in units of mm/s or $g\,cm^{-2}\,s^{-1}$. In the absence of a water table near the surface, v_z is generally positive. Compared to aboveground measurements of estimates of the water vapor flux, the soil – water balance approach has the advantages of ease of data processing and integration, since the soil – water reservoir (SM) automatically integrates extraction rates between observations. The disadvantages are associated largely with a somewhat lower level of measurement accuracy and the difficulty of adequately assessing evapotranspiration during periods of rainy weather. Therefore, its applicability is, to a considerable degree, restricted to regions of relatively high potential evaporation rates and sufficiently well-defined alternations of rainy and dry weather.

2.1.2.1. Precipitation and Interception

The measurement of precipitation N at a site or in a region is generally considered simpler and more straightforward than that of the other terms in the water balance equation. The technical requirements are comprehensively described by Von Hoyningen-Huene and Nasdalack [124] and by Sevruk [125]. The identification

of unequivocal spatial structures should be controlled by means of variogram analysis, which is particularly important in vegetation stands (see Section 3.1.4.3).

Here, marked differences in the pattern of precipitation actually reaching the ground normally develop in many plant communities because of the gross interception of precipitation by the vegetation. Subsequently, precipitation is partly transferred to the soil by channeling down the main streams ("stemflow") and partly by dripping from branches, twigs, and foliage ("canopy leaching"), or it may be lost by evaporation from the wet surface. This latter proportion constitutes the term "net interception." Further differences in the amount of precipitation reaching the ground between plants ("throughfall") are due particularly to the disturbed wind structure and are most noticeable in the case of snow.

In view of the complicated physical nature of net interception, attempts to assess it by means of measurement and by indirect estimations are quite numerous. In the framework of a comprehensive agroclimatological model, BRADEN [126] developed the following interception estimate:

$$N_i\,(R) = a \cdot LAI \cdot \left(1 - \frac{1}{1 + N_0 b / aLAI}\right) \tag{9}$$

where (in the author's notation) $N_i(R)$ is the net interception; $a \cdot LAI$ the saturation parameter, dependent on leaf area index (LAI) and a species-specific maximum interception a; N_0 the above-canopy precipitation; and b the density of vegetation cover. The BRADEN approach has the double advantage of mathematical simplicity and physical foundation, and its validity has been widely tested [127].

With rain, drip or stemflow is usually observed after an area rain total of about 2 mm has been received. However, with freezing rain or snow under conditions favoring retention on the leaves, twigs, branches, and stems (i.e., low wind, temperatures a few degrees below freezing), several times this amount may be accumulated. Stemflow is enhanced by a smooth bark and by branches and leaves that are inclined upwards. Thus, in deciduous (beech) and evergreen (spruce) forests the amounts vary considerably, beech providing much more stemflow and much less interception loss, while oak would have an intermediate position (for greater details, see [2]).

2.1.2.2. Infiltration and Surface Runoff

Horton Overland Flow. Surficial runoff in the sense of Horton overland flow occurs whenever the rate of effective precipitation (i.e., precipitation net interception) exceeds the rate of infiltration ($F*$) and the resultant accumulation of surface water exceeds the pondage capacity ($S*$) at the point of measurement. The most important regulator is $F*$. It is useful in applied hydrology and in relation to pollutant transport to characterize the dynamics of infiltration by a small number of parameters. PHILIP developed a simple physical model of infiltration, which is, however, closely related to more precise diffusion descriptions of infiltration [128].

$$i = St^{0.5} + At \tag{10}$$

where i is the cumulative infiltration at time t, and the constants S ("sorptivity") and A have a physical meaning related to the diffusion analysis of infiltration. The first term on the right-hand side of Equation (10) describes the contribution to infiltration due to capillarity; the second term represents mainly the contribution due to gravity. The differential form of Equation (10) is Equation (11), where v is the rate of infiltration (cm/s):

$$v = \frac{1}{2} St^{-1/2} + A \tag{11}$$

Some values of the infiltration rate (mm/h) for particular soils in specified conditions are given below:

Sand, loess, silt	11 – 7
Sandy loam	7 – 4
Clayey loam, soils poor in organic matter	4 – 1
Clays, alkaline soils (solonets)	<1

These values are much lower than those determined by means of a field rain simulator in the Schönbuch Nature Reserve (Baden-Württemberg), where the use of buffered cylinder infiltrometers proved impossible because of the extremely high spatial variability of the infiltration-relevant soil characteristics. The experimental conditions were such that a constant surface runoff rate was produced by a

constant amount of rainfall when the soil had reached its saturation point. Since evaporation is negligible during the short duration of the experiment in comparison to the rainfall applied (100 – 250 mm/h) and the increment in soil and water storage is assumed to be zero, the difference between precipitation and surface runoff may be equated to infiltration [129]. For two clay soils tested, the minimum infiltration capacity amounted to 58 and 60 mm/h; for sandy soils, 79 mm/h was measured, while the infiltration rates of loamy soils varied between 63 and 76 mm/h. These results are, on the one hand, indicative of a marked enhancement of infiltration due to organic matter and, in particular, desiccation cracks and root voids; on the other hand, they point to high throughflow rates close to the surface (e.g., piping). As a consequence, no differences in runoff characteristics could generally be found on soils in coniferous, broadleaf, or mixed forests. Variation in the runoff rates was high when the soils were initially dry, but low when the soils were wet. A comparison of these minimum infiltration rates with the maximum net precipitation rates recorded within the last hundred years leads to the conclusion that surface runoff is an exceedingly rare phenomenon in temperate forests due to preferential seepage.

Horton overland flow appears to be a common process in semiarid and arid regions, where precipitation intensities are high and the infiltration capacity of the sparsely vegetated soil is low. It is further caused or intensified by the development of a crust on the soils because the surface layer becomes compacted and the pores blocked as a result of the redistribution of soil particles following raindrop impact. Crust formation due to lateral iron translocation is a particularly widespread phenomenon in ferric luvisols of the semihumid tropics, where it largely contributes to enhance pediplanation processes.

Saturated Overland Flow. In temperate environments with normally modest precipitation rates and well-structured soils, Horton overland flow is the exception rather than the rule, except under certain conditions of cultivation and when the ground is frozen. In temperate environments, all the pore spaces may become filled with water after a period of prolonged rainfall, thus saturating the soil. At this point the water table has risen to the surface and the effective infiltration capacity is consequently reduced to zero. Subsequent rainfall runs off directly across the surface of the slope as saturated (or saturation) overland flow. This situation is likely to come about toward the base of a slope or in microtopographical depressions on a slope where both local infiltrations and throughflow received from higher up the slope contribute to soil moisture. Smith and Parlange [130] describe simple relationships that enable saturating or ponding times to be estimated from values of saturated hydraulic conductivity K_s and sorptivity s. In Morocco Imeson [131] found that the amount of rain required to pond the soil p_r could be estimated reasonably well with one of these equations, namely,

$$\int_0^{t_{p_r}} p_r \, dt = \frac{A}{K_s} \ln \frac{r_p}{r_p - K_s} \tag{12}$$

where A is 0.5 s^2 and r_p is the rainfall intensity.

Because of the number of boundary conditions operative in runoff, the latter varies considerably with the amount, intensity, and duration of precipitation, as well as with slope configuration and soil fabric, which determine the degree and extent to which pondage can occur [129], [132], [133]. In natural situations, the slope is rarely constant and, while runoff tends to reduce soil water recharge at the top of the slope and increase it at the bottom, minor changes of slope generally modify the slope – runoff interrelation. Table 2 provides some runoff figures from two sites in the Federal Republic of Germany. Bochow is representative of loamy luvisols developed from Weichselian till, while Müncheberg is characterized by a podzolized cambisol on coversand overlying Saalian till.

Table 2. Hydrometeorological characteristics of two ploughland sites in northeastern Germany for 1961 – 1965 (after [2])

Characteristic	Müncheberg	Bochow
Number of erosion-inducing showers	30	39
Precipitation, mm		
Median value	14.8	11.8
Mean extreme value	23.6	18.4
Absolute extreme value	34.8	25.2
Runoff, mm		
Median value	1.2	2.1
Mean extreme value	3.3	5.1
Absolute extreme value	10.2	8.1

2.1.2.3. Deep Drainage

The deep-drainage term in balance Equation (7) comprises throughflow and groundwater flow and can be equated to a vertical flow that, in turn, may be calculated from hydraulic conductivity and soil water potential data. The normal equation for vertical flow of water v_z is

$$v_z = K + K\frac{\delta h}{\delta z} \tag{13}$$

where K is the hydraulic conductivity (cm/s) and $(\delta h/\delta z)$ is the rate of change of soil water suction (h in cm) with depth (z in cm). Soil water suction is derived from the soil water potential ψ (dyn/cm^2) by the relationship $h = -\psi/\varrho_W g$, where ϱ_W is the density of water and g the vertical acceleration due to gravity. Unless h is very small, $\delta h/\delta z$ is usually much greater than unity so the K term in Equation (13) is often negligible [122]. Under these circumstances, the deep-drainage term of the water balance equation is given by

$$GWR + TF = \int_{t_1}^{t_2} v_z \cdot \mathrm{d}t \tag{14}$$

where $(t_2 - t_1)$ is the time between observations [134], [135].

In other situations, a net upward flux of soil water into the root zones can occur from wetter underlying soil horizons or, in particular, from a water table closer to the surface. For comprehensive reviews of methods available for the determination of deep drainage with a particular emphasis on groundwater recharge, see [136–140].

Under certain soil conditions, diffuse water movement through the intergranular pore spaces and voids may be supplemented by concentrated turbulent throughflow in networks of pipes. These result from large voids that exist in many soils and are enlarged by soil fauna (e.g., mice, rats, hamsters, moles, weasels, ground squirrels) and the growth and decay of roots. Frequently, soil pipes develop at the interface between organic soil and the underlying mineral soil. Discharge in completely filled pipes varies depending on pressure and gravity potentials, and in partly filled pipes in response to the gradient of the water surface. Usually, therefore, pipe flow velocity is much more rapid than that of matrix flow. Table 3 quotes estimates of flow velocities. From these figures, pipe flow may be seen to attain considerable importance in chemical transport, although the distances covered are normally small in comparison to channel flow. Piping is perhaps more strongly associated with semiarid areas than with humid regions. Drainage and slope development in badlands all over the world are frequently dominated by piping.

Table 3. Flow velocities along different routes in a catchment (after [141])

Type of flow	Flow route	Velocity, m/h
Surface	channel flow	300 – 10 000
	overland flow	50 – 500
Soil flow	pipe flow	50 – 500
	matrix throughflow	0.005 – 0.3
Groundwater flow	limestone (jointed)	10 – 500
	sandstone	0.001 – 10
	shale	10^{-8} – 1

2.1.2.4. Soil Water

Measurement of changes in soil water storage is conducted most accurately by the use of weighing or hydraulic lysimeters, provided they are properly designed and sited [142]. Lysimeters cannot be used, however, when the nature of the species composition, the spatial structure of the vegetation cover, the depth and ramification of the root system, or other factors make it impossible to simulate the natural environment inside the lysimeter itself. In such cases, determinations of changes in soil water storage at different points in the plant community provide the only technique for evaluating $\Delta(SM + SW + GW)$. Soil water sensing equipment may still fall short of operator requirements, although marked advances have been made since the 1980s. Probably the most commonly used techniques, at the present time, are those of neutron moderation and tensiometers or tensiographs.

2.1.3. Energy Balance of Ecosystems

The disposition of radiant energy at the surface of the earth is of prime importance for

understanding soil – water balances and the related chemical transport and transformation processes. A formalized transcription of the energetic relationships yields the following form of the energy balance equation:

$$R_n + H_s + H_a + r_{ET} = 0 \tag{15}$$

In this equation, which summarizes the solar energy cascade with its numerous regulation and transformation components, any form of energy that is flowing toward the surface is considered positive and any form that is moving away from it is considered negative. R_n is the *net radiant flux*, H_S is the *heat flow* in soil at the surface, H_a is the *sensible heat* transfer through air at the surface, and r_{ET} is the transfer rate of *latent heat* due to evapotranspiration. Conventionally, all terms are expressed in joules per minute and square centimeters; $4.19\,\mathrm{J\,cm^{-2}\,min^{-1}}$ equals ca. 1 mm of water depth evaporated per hour.

2.1.3.1. Net Radiation

The earth's surface receives short-wave and long-wave radiation from the sun – some of which is lost through reflection – and long-wave counterradiation from the atmosphere, while itself emitting long-wave radiation. Whereas photochemical reactions are controlled mostly by short-wave radiation, the diurnal variability of surface temperatures and the related energy fluxes are very much under the influence of long-wave radiation. Thus, the net radiant flux R_n may be derived from the short- and long-wave radiation balances:

$$R_n = ES\,(1-\alpha) + R_c - \varepsilon\sigma T^4 \tag{16}$$

where the solar radiation ES is the sum of direct beam radiation ES_S and diffuse radiation ES_D, each term comprising short-wave and solar long-wave components; R_c is the long-wave counterradiation of the lower atmosphere; $\varepsilon\,\sigma\,T^4$ the long-wave radiation from the earth's surface (Stefan – Boltzmann radiation); and α the reflectivity. Regionally, the net radiant flux of the earth's surface varies considerably with a general trend toward a positive balance or surplus in low latitudes and a negative balance or deficit in high latitudes (for details, see [17]). Factors such as cloudiness and atmospheric humidity, which in conjunction with aerosols affect the transmission of both solar and terrestrial radiation, and the radiative properties of the soil and vegetation canopy create the spatial variation in radiation balance over the earth's surface.

2.1.3.2. Soil Heat Flow

The rate at which heat is transferred downwards into the soil and subsurface substrate (H_s) is directly related to the nature and efficiency of the distribution mechanisms. In solids, heat is redistributed by conduction, and the flow rate depends on *thermal conductivity*. Units are watts per meter per degree Celsius ($\mathrm{W\,m^{-1}\,{}^\circ C^{-1}}$) or joules per centimeter per second per degree Celsius ($\mathrm{J\,cm^{-1}\,s^{-1}\,{}^\circ C^{-1}}$). Under steady-state conditions, the flow of heat ($\partial Q/\partial t$) is related to the temperature gradient ($\partial\Theta/\partial x$) and the thermal conductivity λ by

$$H_s = \frac{\partial Q}{\partial t} = \lambda\frac{\partial\Theta}{\partial x} \tag{17}$$

A major problem in soils is that steady-state conditions are rarely achieved and thermal conductivity is a complicated function of granulometry, mineralogical composition, compaction, and water content. The conventional determination of thermal conductivity is consequently fairly difficult. An alternative parameter, *thermal diffusivity*, is used, which is given by $\lambda/(c\varrho)$, where c denotes the specific heat and ϱ the density. Units are square meters per second. For a homogeneous medium, thermal diffusivity defines the rate at which temperature changes ($\partial\Theta/\partial t$) take place:

$$\frac{\partial\Theta}{\partial t} = \frac{\lambda}{c\varrho}\cdot\frac{\partial^2\Theta}{\partial x^2} \tag{18}$$

2.1.3.3. Sensible Heat Flow in the Lower Atmosphere

The magnitude of the heat flow into the air at the surface H_a can be obtained by a difference when the other components of the energy balance in Equation (16) are measured, or it can be determined directly. Among the latter approaches, two methods, the aerodynamic method and the

Sverdrup – Albrecht method merit particular attention.

The *aerodynamic method* is based on very precise determinations of the vertical temperature and wind profiles, and involves a horizontal homogeneity of the surface over considerable distances in the luff of the measuring station.

The *Sverdrup – Albrecht method* determines either H_a or ET as components of the energy balance in Equation (19)

$$H_a = \frac{H_a}{ET}(R_n - H_s) \cdot \left(1 + \frac{H_a}{ET}\right)^{-1} \tag{19}$$

The ratio H_a/ET (Bowen ratio) can be estimated from measurements of the vertical gradients of temperature ($\Delta\Theta/\Delta z$) and vapor pressure ($\Delta e/\Delta z$) above the surface.

2.1.3.4. Latent Heat Flux

The latent heat flux can be estimated as a result of the vaporization or condensation of water. Consequently, five general methods are used to evaluate the water vapor flux caused by evapotranspiration.

Analogous to Equation (19), the *Sverdrup – Albrecht method* may be used to determine ET:

$$ET = (R_n - H_s)\left(1 + \frac{H_a}{ET}\right) \tag{20}$$

Thornthwaite and Holzman [143] suggested

$$ET = \frac{\varrho k (U_2 - U_1)(q_1 - q_2)}{[\ln(z_1/z_2)]^2} \tag{21}$$

where q is the average water vapor content, ϱ the air density (g/cm^3), U the average wind speed (cm/s), z the average elevation above surface (cm), and k von Karman's constant (0.4).

A *continuous record of water vapor convection by means of eddy-correlation techniques* as described by Dyer [144] yields estimates of ET by

$$ET = \frac{1}{t}\int_0^t \varrho w q \, dt \tag{22}$$

where ϱ denotes air density, w the momentary vertical wind speed, and q the instantaneous value of water vapor concentration. The problem of measuring ET as the time average of the vertical flux of water vapor thus becomes one of designing instrumentation capable of measuring the turbulent air motion and structure of q. This involves equipment whose response time is sufficiently short to take account of all frequencies in the turbulent spectrum contributing significantly to the flux. This requirement depends on both the height of measurement and the stability of the air, which means, in general terms, that the sensing elements should respond adequately to signals with a period of 1 s.

If all terms of the energy budget are known except the flux due to evaporation (or evapotranspiration), the latter can be obtained by a *difference*. Finally the latent heat flux can be found by *direct measurement*, i.e., by means of weighing lysimeters on the local scale or as the difference term of the water budget of a drainage system on the regional scale.

2.1.3.5. Efficiency of Photosynthesis

In comparison to the above components of the energy balance summarized in Equation (15), the absorption of photosynthetically active radiation in the plant cover plays a quantitatively minor role. Yet, it furnishes useful information on the amounts of solar energy available for photochemical reactions at the surface of soil and vegetation under natural conditions. A quantitative description of the absorption process is provided by

$$dP = \gamma (ES)_v \, s \, dz, \tag{23}$$

where P is the rate of absorption, γ is the coefficient of absorption of photosynthetically active radiation (i.e., wavelength ranges from 400 – 480 nm to 640 – 690 nm); $(ES)_v$ is the incident direct beam and diffuse short-wave radiation; s is the specific leaf surface (i.e., the surface of leaves in a unit volume); and z is the vertical coordinate counted upward [18].

According to Monteith and Szeicz [145], the daily energy rates required for gross assimilation are about 28.5, for respiration 6.7, and for net assimilation 21.3 J cm^{-2} d^{-1}. This means that normally the photosynthetic efficiency of the vegetation cover is in the order of magnitude of 1 – 2 % of the total incident radiation. These

findings were corroborated by numerous authors. Examples of studies from different parts of Central Europe are, for instance, [19] and [146]. From the purely quantitative budgetary point of view this may appear little, but with regard to bioproductivity and photochemical transformation reactions the situation is quite different. A number of compounds (e.g., various chlorinated aromatics) show distinctly higher conversion rates if adsorbed on particulate matter than if deposited as solids or on thin films [147]. This can be attributed to a bathochromic shift, changes in the relative extinction, the appearance of new absorption bands as a consequence of adsorption, and finally fixation of the dispersed molecules in the adsorbed phase resulting in an intensified compound – oxygen contact.

2.1.4. Nutrient Cycles and Productivity of Terrestrial and Aquatic Ecosystems

Speaking about nutrient cycles means considering how the same atoms of elements move through different components of nature or different biota, and participate in different kinds of reactions (Fig. 8). In principle, these are always chemical reactions; however, the conditions driving them vary highly if embedded in biochemical, biological, or ecological structures. A typical feature of the organic world is the hierarchy constructed of levels of increasing complexity (Fig. 9). In such a hierarchy, the control of processes is both bottom-up, from the low levels to high ones, and top-down, from the higher to lower levels. Biological reactions are controlled by several mechanical, chemical, and neurological mechanisms, which depend on the internal and external environment of biota. An example is the formation of urine in kidneys. In ecological reactions, the conditions for biological, biochemical, and chemical reactions are driven by population cycles of organisms, by mutual reactions of the environment and biota, and by interactions among biota themselves.

Biological production is based on the uptake of nutrients, but external conditions such as light, temperature, and oxygen have major effects. Production is the output of organic matter formation by plants, the primary producers, and of transformation by other groups of biota. Biomass is the organic mass of organisms, which can be expressed as fresh weight, as dry weight, as protein content, or in energy equivalents. Biomass is the standing stock, which is not necessarily identical with production. Deciduous forests in temperate regions, for example, produce yearly the biomass of leaves that then decay in fall. The next year, a new leaf biomass is formed.

In the following, nutrients and biological production are described separately for the sake of simplicity. However, they are shown to be inseparably interrelated. A distinction is made between terrestrial ecosystems (those inhabiting land) and aquatic ecosystems (those inhabiting water).

The effect of human activities, particularly of industry, on the environment is enormous. Humans are at present the dominant driving force on earth. They must take care that this force is not misused and is not driving humanity to extinction.

2.1.4.1. Nutrients

Nutrients are defined as those chemical elements that are essential for the construction of organisms. Depending on the proportion of the organism biomass that they represent, nutrients are usually divided into two classes: (1) macronutrients and (2) micronutrients or trace elements. *Macronutrients* represent major components of the biological material and are needed in large amounts. Usually, C, N, P, K, S, Ca, and Mg are considered macronutrients. *Micronutrients* are needed only in small amounts; micronutrients include Si, Mo, Cu, Zn, Mn, Fe, B, and Cl. The needs of organisms for elements belonging to the same class differ by a factor of ten. An indication of the ratio of the first three macronutrients in organisms is given by the stoichiometric ratio of the organisms' bodies. The average elemental composition (by weight) of aquatic autotrophs, for example, is about C : N : P = 106 : 16 : 1. In land plants the average ratio of C : N : P corresponds to 250 : 10 : 1 according to data in [21], and the entire set of macro-elements will give a C : N : P : K : Mg : S ratio of 250 : 10 : 1 : 5 : 5 : 1 : 0.5. Micronutrients are present in land plants in lower amounts (Fe 100, Mn 50, B 20, Zn 20, Co 6, and Mo 0.2 μg per gram dry weight). However, their ratios can vary

Figure 8. Nutrient cycling and productivity of ecosystems production decreases in relation to successive steps of the trophic chain (producers > herbivores > predators) (after [20], modified)

widely in individual plants (see, e.g., [148] for aquatic plants).

Chemical elements usually are not taken up as such by plants; rather, chemical compounds (e.g., C in the form of CO_2) are. Plants are now recognized to optimize their uptake. For example, in selection between nitrates and ammonia, the energetically more favorable ammonia is taken up first. Only some compounds of phosphorus are bioavailable [22].

A typical curve for the kinetics of nutrient uptake is given in Figure 10, which also shows that an element essential for the life of organisms may have a negative effect if it is present in excess quantities. In agriculture this is known as overfertilization. Plants need at least the first three macronutrients (C, N, P) simultaneously. The theory of limiting nutrient states that the nutrient in shortest supply represents the bottleneck. The uptake of all macronutrients is driven by the limiting one, the rest being taken up proportionally to the total needs.

Inorganic nutrients are taken up only by plants with photosynthetic pigments that use solar energy for the construction of highly structured organic matter from more simple inorganics. Such plants are called *autotrophs*; *heterotrophs* are organisms bound to organic matter formed primarily by autotrophs, but possibly transformed by other heterotrophs (e.g., carni-

Figure 9. Hierarchy of biological organization; looking at selected objects of nature with successively larger or smaller magnification involves a simultaneous change of view

Figure 10. Kinetics of nutrient uptake by organisms
Organismic growth depends predictably on nutrient concentration, following a relationship known from enzyme kinetics.

Figure 11. Nutrient (nitrogen) cycle in a man-made landscape (after [20])

vores). Bacteria, in this connection, are known as *decomposers*. They decompose matter to mineral components; bacteria belong to a larger group of destruents, degrading dead organic material, the so-called detritus.

2.1.4.2. Nutrient Cycling in Ecosystems

Two basic types of cycles can be distinguished: the short-circuit cycle in natural ecosys-tems (see Fig. 8) and the open cycle in agricultural ecosystems (Fig. 11). In natural ecosystems, nutrients circulate rapidly among the organisms,

soil, and groundwater. Soil constantly coveredby vegetation retains water with the dissolved nutrients. The vegetation cover also retains humidity. Evaporation creates backflow from the atmosphere as rain. Soil is rich in organic matter, which keeps the water capacity high. Therefore, nutrient loss from vegetated soils is low. Simultaneously, soil erosion and washout of nutrients are minimized.

In today's agricultural and inhabited landscapes, the situation is drastically different. The soil is barren or loosely covered, at least for a part of the year. Because of lack of rhizosphere, it is subject to high erosion and flushing out of nutrients to streams and rivers and, consequently, to lakes or sea. The soil is continuously deprived of organic matter, which decreases its water retention capacity. Instead of a short-circuit, an open cycle is observed, with considerable nonreversible losses. In the United States, soil erosion was estimated in 1968 and 1980 to represent 36×10^9 kg/a, about one-half of which originated from agriculture.

The opening of the cycle of organics and nutrients occurred in the Middle Ages when the increasing accumulation of people in towns caused diseases to spread. The construction of sewers disrupted the natural cycle, the original backflow of organic remnants and nutrients to the soil being diverted.

An experiment showing which major changes are produced by deforestation was obtained on the Hubbard Brook Ecosystem [4], [23]. Trees were logged within the entire watershed, and the outflow and its chemical composition were carefully measured. An increase in soil erosion and leaching of nitrogen, phosphorus, and sulfur to groundwater and streams was observed. Because water flux through the soil has increased, the soil loses its fertility. The organic forest floor rapidly decomposes and eventually disappears. The variability of flow in streams increases, with much more transport of the streambed produced during larger flows. However, the average flow decreases. Nitrogen released to the atmosphere during burning of remains has negative effects on the atmosphere. Reradiation from barren soil creates ground-level frosts on clear nights. Soil temperature is significantly increased on hot days.

Carbon Cycle. The global cycling of carbon is gaining in importance, not only because of plant nutrition but mainly because of its increasing concentrations in the atmosphere and the oceans. Because of the increase of several "greenhouse" gases – among which CO_2 plays the leading role – a global change in world weather conditions is expected. Carbon is essentially exchanged among the four reservoirs shown in Figure 12, where the past (in the atmosphere) and present reserves and flows are also given. The importance of forests and oceans as balancing elements in the CO_2 budget is enormous.

Figure 12. Major carbon reservoirs (after [24])

Nitrogen Cycle. Basic transformation processes in the terrestrial cycle of nitrogen are shown in Figure 13. Two pathways lead out of the short-circuiting between soil, crops, and animals: to the atmosphere and to water. Losses to the atmosphere have two dominant sources: industry, which releases NO_x; and agriculture, specifically animal husbandry, which produces NH_3. Both gases contribute to the greenhouse effects. Losses of nitrogen to waters also have negative consequences. Figure 14 shows the enormous rise in concentration of nitrates in water bodies in intensively cultivated landscapes of Europe and North America. Since the pristine state, the concentration has increased by a fac-

Figure 13. Soil nitrogen cycle (after [25], modified)

tor of ten and is occurring in both surface and groundwater. Most of this nitrogen increase is attributable to agriculture, for which it represents enourmous economic losses because of unutilized fertilizers. World fertilizer use increased from about 5 kg per capita in 1950 to 28 kg in 1985 [151]. The consequence of this fertilization of waters is an increased growth of aquatic vegetation, particularly of nuisance algae. In drinking water supply, excess nitrates result in hygienic problems, among them the deadly infant disease methemoglobinemia. For these reasons, every country has standards for the maximum permissible concentrations of nitrates in drinking water. The problem of cheap extraction of nitrogen from water is far from being solved on a global scale, although technological nitrogen-elimination processes are known. The nonsensicality of losing amounts of costly nutrients from agriculture on the one hand and eliminating them from waters at high costs on the other seems evident.

Phosphorus Cycling. A popular representation of the phosphorus cycle is given in Figure 15. Similarly to C and N, short-circuit cycling is characteristic of natural undisturbed vegetated landscapes. An open cycle with losses, mainly to waters, typifies agricultural and town environments. The difference from the previous cycles is that no phosphorus gas phase occurs. In organisms, phosphates are oxidized to produce energy in cellular respiration, and the phosphate is released in urine or similar waste back to the environment. When phosphorus compounds (particulate P, adsorbed P, dissolved orthophosphates, inorganic polyphosphates, organic phosphorus dissolved in the water phase) enter waterways, they enrich – indeed, overenrich – aquatic ecosystems. In waters, the processes of phosphorus uptake by aquatic flowering plants and microflora as well as processes of P immobilization and microbial synthesis are inadequate to utilize these amounts. Besides nuisance growth, considerable amounts of P-rich sediments accumulate in estuaries, lakes, and reservoirs. From water, little natural return to the land occurs. The sources of phosphorus for water are listed below:

Figure 14. Trends of nitrate in freshwater and fertilizer use
A) Mean winter – spring concentrations of nitrate in Esthwaite Water and Blelham Tarn (Lake District, United Kingdom); B) Mean annual nitrate concentrations at Walton on Thames (United Kingdom), after [149]; C) Mean annual nitrate concentrations in the Slapy Reservoir (River Vltana, Czech. Republic), and related fertilizer use in the drainage basin [150]; D) Mean global fertilizer use per capita in 1950 – 1984 [151]; crosses represent newer data [26]

Natural surface load	0.07 – 0.12 kg/ha
Atmospheric load	0.4 – 1.2 kg/mm
From agricultural areas	up to 1.8 kg/ha
Livestock sewage	up to 13 kg per capita cattle
Sewers	0.85 kg per capita dweller
Septic tanks	0.14 kg per septic tank
Municipal sewage	1.1 kg per hectare of town area

Although great differentiation exists locally, two sources of phosphorus seem to dominate in the developed world: detergents and soil erosion. Phosphorus applied as fertilizer does not go into waterways in significant amounts unless some scattering from stores or spreading during aircraft application occurs.

2.1.4.3. Productivity of Ecosystems

Major biomes of the world are represented in Figure 16. The total biomass of plants on the globe is estimated to be 1.84×10^{15} kg [28]. The value is rapidly diminishing because of forest clearing, soil salinization, and desertification. In tropical countries of America, Africa, and Asia, the rate of loss represented 37, 48, and 40 %, respectively, between 1980 and 1985 [29]. Typical feedback between the nutrients and organisms is shown in Figure 17, which illustrates the dynamics of natural systems.

However, nutrients are not the only decisive agents for biological production. As evident from the summary photosynthetic equation

$$6\,CO_2 + 6\,H_2O \xrightarrow{\text{Energy}} C_6H_{12}O_6 + 6\,O_2 \qquad (24)$$

Figure 15. Phosphorus cycle (after [20])

energy (usually solar energy) and water are necessary. Like chemical reactions, biological reaction rates are also affected by temperature. The difference is that life is confined only to some −50 to +50 °C. Characteristic shapes of light and temperature dependence of organismic growth are given in Figure 18. For the above reasons the fate of nutrients is highly dependent on geographical position as well as seasonal and daily changes, as shown in Figure 19.

Productivity of Terrestrial Ecosystems. A distinction is made between natural and the agricultural production, although temperate forests are now also cultivated. Quantitative data on primary production around the world were elaborated in [28], [152]; data on sites where primary and secondary production was measured simultaneously are summarized in [30], [153]. The results of these studies are given in Table 4. Such estimates are methodologically very difficult, and some of them might be highly biased. Only the net aboveground production was measured; belowground production is known to represent up to five times as much as aboveground [31]. Net production is distinguished from gross production in that it does not include organic matter produced but used immediately for maintenance (respiration, excretion). The range of values for 104 sites was es-

Figure 16. Major biomes of the world (after [27])

Figure 17. Essential processes of ecosystem dynamics
A) Time development of a population of autotrophs and heterotrophs in a nutrient-limited environment 1) At time t_1 (e.g., in winter) nutrients (curve a) are high and autotrophs (curve b) low, due to low temperatures. When autotrophs start to appear, they grow quickly and take up nutrients rapidly. 2) At time t_2, growth ceases, being severely limited by the decreasing quantity of nutrients (see inset). 3) Heterotrophs (curve c) appear with retardation, because their life cycles are long and at the beginning their abundance is limited by low food supply (i.e., low amounts of autotrophs on which they feed). At time t_3 autotrophs decrease, being heavily grazed on by herbivores (heterotrophs). Nutrients are regenerated both from senescent and decaying autotrophs and from excretion, defecation, and nutrient release (as in Fig. 17 B)
B) Main processes in the nutrient-productivity cycle. Losses are represented by flushing nutrients into groundwater and streams.

timated as 30 g fresh weight per square meter and year for a desert to 7050 $g\,m^{-2}\,a^{-1}$ for a tropical forest. The average estimates for various ecosystems range from 0 – 10 g dry weight per square meter and year for extreme desert through 10 – 250 for deserts and 400 – 2000 for boreal forests up to 1000 – 3500 for tropical rain forest and 800 – 6000 g dry weight per square meter and year for swamps and marshes. Table 4 shows that forests in general are the most productive ecosystems. Column 3 also shows that a high proportion of the primary production in nature is consumed by herbivores, be they insects, small rodents, or large ungulates. On average, 1.3 to 64 % of primary production is consumed in different biomes, with by far the highest pro-

Figure 18. Light and temperature dependence of organismic growth and related feedback mechanisms
A) Typical shapes (equations not shown) of the dependence of plant growth on light and temperature. The dotted line shows the dependence typical for a chemical reaction (Arrhenius curve). B) In contrast to chemical reactions, which follow a fixed curve, the organisms are capable of adaptation to changing conditions. The two curves show changes for low (a) and high (b) light and low (a) and high (b) temperature conditions, respectively. Within the pertinent range of conditions the adapted organisms have the same high performance. However, full compensation is not always possible, as the temperature case shows. C) Feedback effect of growth on light (left) and temperature (right). In the case of light the feedback is negative; for temperature, either positive (increase of temperature, e.g., in water where more radiation is absorbed by microscopic algae) or negative feedback relationships (decrease of temperature by shading in forests) are possible

portion in tropical grassland. The primary production taken up is converted to herbivore production with an ecological efficiency (expressed as the amount of primary production converted to herbivore production) of about 0.35 %. The efficiency of herbivore utilization of primary production calculated from columns 3 and 4 results in an average value of 0.93 %, with a range between 0.09 for tropical grasslands and 13.3 % for salt marshes. Two types of ecological cycles in terrestrial ecosystems are distinguished in [31]: a short one, where most of the primary production

Figure 19. Adaptation of populations to nutrient supply and competition for nutrients
A) Populations adapt to low-nutrient conditions, as indicated by increasing slope of the curve. Population 1 living in high-nutrient conditions shows a lower initial slope of the curve, while population 2 living in low concentrations shows a high initial slope, enabling it to utilize low concentrations more efficiently
B) Species compete for nutrients. In a certain condition range, one or the other species dominates, depending on the range in which the curve reaches the highest values.

is immediately decomposed, while in the long one, herbivores not only consume a large part of primary production but also are preyed upon by carnivores and a complex food web originates. In Table 4, column 3, only temperate forests show the short cycle, with only about 1 % of primary production being consumed by herbivores. In all other instances the primary production consumed is of the order of magnitude of 10 %. For tropical grassland, seemingly the most complex system, more than half of the primary production is consumed by herbivores. Table 5 gives exam-

Table 4. Data on primary and secondary (herbivore) production of natural ecosystems in different biomes (after [153], modified) [a]

Ecosystem	Prim. prod. [b]	Biomass [c]	Consumption [d]	Herbivores [e]	Efficiency [f]
Desert	403	1	32 (7.9)	0.1	0.02
Tundra	257	0.5	16 (6.2)	0.2	0.07
Temperate grassland	1181	1	161 (13.6)	14.6	1.23
Temperate old field	1352	2.2	95 (7.0)	10.3	0.76
Tropical grassland	2694	8	1725 (64.0)	1.5	0.06
Temperate forest	5032	1.2	64 (1.3)	0.8	0.02
Tropical forest	5400	17	591 (10.9)		
Salt marsh	4328		345 (8.0)	46.0	1.06
Average	2276	8.1	861 (37.9)	8.0	0.35

[a] Values are given in grams of fresh weight per square meter and year.
[b] Prim. prod. = net aboveground annual plant production.
[c] Herbivore biomass in grams of fresh weight per square meter and year.
[d] Amount of primary production consumed by herbivores. The percentage of primary production being consumed by herbivores is given in brackets.
[e] Annual production by herbivores.
[f] Ecological efficiency, i.e., the percentage of primary production converted to herbivore production.

ples of net aboveground primary production of agrarian ecosystems and secondary production of domestic livestock compared to game.

Table 5. Examples of net aboveground primary production of agricultural eosystems and production of domestic livestock per area as compared to wild animals (data from [10], [23])

Primary production, kg dry weight per square meter and year		
Crop	World average	Maximum per country
Wheat	0.4	1.3
Corn	0.7	1.3
Rice	0.6	1.5
Potatoes	2.5	4.6
Soybean	0.35	0.6
Sugarcane	0.9	3.3
Sugar beet	2.0	
Secondary production		
Type of animals	Weight gain, kg fresh weight per day	Biomass, kg/km^2
Sheep	0.05	
Cattle	0.14	
Thomson's gazelle	0.06	
Topi	0.20	
Wildebeest	0.24	
Domestic livestock		10 000 – 27 000
Domestic livestock in East Africa		10 000 – 14 000
Wild ungulates in East Africa		61 000 – 87 000
Bison		12 000 – 17 000
Black tailed deer in California		9 200

Surprisingly, comparison of Table 5 with Table 4 shows that natural production and agricultural production are not much different, if one ignores the extreme energy needs to achieve high agricultural yields [154]. Often the fossil energy input is greater than the energy content of the food harvested [32]. According to [33], for an eightfold increase in yield of major crops, a twentyfold increase in energy applied is needed. The idea that much more output is obtained when artificially cultivating domestic livestock is not supported by these data. The use of natural vegetation by natural livestock is far from inefficient. That was recognized in tropical countries and became a political issue in opposition to what was exported from the developed countries as the "green revolution." The green revolution appears to lead to the continuing poverty of poor countries. They are made dependent on Western technology and on energy sources not available at home, without adequate rewards. The simultaneous trend for sustainable development leads to major revisions of prevailing ideas concerning agricultural production.

Productivity of Aquatic Ecosystems. The primary production of fresh waters may be divided into two groups: (1) production of flowering plants living in shallow water of marshes, swamps, and along the shores of lakes and slow-flowing streams; and (2) microflora inhabiting primarily the open lake and slow river central regions. Microflora consists of several groups of microscopic algae and species of cyanobacteria (also called blue-green algae). These free-floating organisms are called phytoplankton.

The transition between land and water belongs to the most productive plant environments: no water deficit exists; nutrients are obtained both from rich aquatic soil and from water. Under comparable geographic conditions, the highest production among all vegetation is obtained in aquatic macroflora. The dependence of aquatic primary production on geographical position is due to a combination of effects such as light and temperature. For phytoplankton, conditions of mixing in lakes dependent on geographical latitude and altitude are decisive. During the annual cycle, lakes undergo periods of intensive deep mixing to the bottom, as well as periods of stratification. During summer stratification, upper layers become warmer than deeper ones, and intensive mixing is confined to several top meters. The density difference between warm top and cold bottom layers is usually sharp. At a certain depth, a jump in temperature occurs between the two basic layers called the mixing layer (thermocline) and the hypolimnion. The depth of the mixing layer affects primary production. Algae moved within this layer periodically encounter high light intensity when taken to the water surface and reduced or no light when mixed to depths. Greater lakes are usually clearer and mixed to greater depths due to higher wind stress; their primary productivity is lower than that of shallow lakes with comparable nutrients.

The most important determinant of lake productivity is nutrient input. In the 1960s, controversy existed – mainly between representatives of the soap and detergent industry and limnologists studying lakes – whether carbon, nitrogen, or phosphorus is the nutrient most often limiting aquatic primary production. The situation is now clear: depending on the mutual relation among C, N, and P any of them can be limiting, as can several micronutrients. However, in most lakes at present, phosphorus is the limiting agent, since nitrogen is usually supplied from human activities in excess. Carbon can limit in instances of an excess of both nitrogen and phosphorus; carbon deficiency is due mainly to limited exchange of CO_2 between water and atmosphere. This is the case in highly fertilized fish ponds. A systematic difference exists between fresh water on the one hand and brackish and marine waters on the other: in the latter, nitrogen limitation prevails. Instances of limitation by micronutrients are reported rarely, particularly from regions without human activities, where the lack of some elements is geologically conditioned [34].

Table 6. Primary and secondary production in fresh waters, based on different sources and data obtained mainly during the International Biological Program [5] (for more detailed data see [31])

Type of water body	Macroflora Aboveground primary production, kg dry weight per square meter and year	Average biomass, kg dry weight per square meter and year
Lakes and streams	0.1 – 3.0	0.02
Swamps and marshes	0.8 – 8.5	1.5
	Microflora (phytoplankton)	
Phosphorus and nitrate concentrations, µg/L	Primary production, kg dry weight per square meter and year	Average biomass, g dry weight per square meter
Low P (<5) and N (<250)	0.015 – 0.09	0.4 – 2.0
Medium P (<30), N (<500)	0.075 – 0.3	2 – 5
High P (>30), N (>500)	>0.43	>5
	Type of water body fish production,∗ kg fresh weight per square meter and year	
Small lakes	0.002 – 0.18	
Great lakes	1 – 7	
Tropical lakes	2 – 250	
European fish ponds	500 – 850	
Chinese fish ponds	500 – 7500	

∗ Fish production is estimated from harvested production. According to recent estimates harvested production represents in lakes about 10 % of total production and in culture about 50 %.

Table 6 gives some ideas of the primary production of fresh water depending on phosphorus and nitrogen concentrations. In addition, there is a geographical differentiation of phytoplankton primary production at similar conditions of nutrients. In Arctic and Antarctic lakes values between 0.002 and 0.07 kg dry weight per square meter and year were observed. In alpine lakes the lowest values observed are similar to those in the Arctis but maximum values up to 0.2 are reached. For temperate and tropical lakes the ranges are 0.004 – 1.8 and 0.06 – 5.0, respectively. Some data on herbivorous production, represented by fish, are also indicated. The biomass of phytoplanktonic algae is about three factors of ten lower than in macrophytes, whereas production is similar. This is due to the short life cycle and high turnover rate of microscopic algae. Under intensive artificial cultiva-

tion, some algal species have produced up to 8 kg dry weight per square meter and year.

2.2. Terrestrial, Lotic, Lentic, and Wetland Ecotones

A boundary in nature may be created by discontinuities in the external influences that control the ecosystems or by discontinuities in the functional network of the systems themselves. Consequently, a wide spectrum of equilibrium system responses to values of environmental gradients exists.

In Figure 20 A the response of the ecosystem as characterized by one indicator variable is as smooth and linear as the changes in gradient; Figure 20 B depicts an abrupt break in response, probably due to a threshold response in one of the components of the ecosystem. In Figure 20 C the response has a twist, indicating that the system can have two stable equilibrium states. In these cases the ecosystem state and behavior with respect to driving variables depend on the history of the systems (hysteresis). Hysteresis plays a major role in catastrophe theory. In Figure 20 D the system has two stable states and can display multiple internal reactions to take on one or the other.

In more abstract or unifying terms the individual response curves of Figure 20 can be considered as a continuum of ecosystem responses to an environmental variable. Thus, the various responses grade into one another depending on internal reactions and autonomous features of the ecosystem. The environmental gradients can be continuous or discontinuous to form a variety of pattern that, together with the response of the ecosystems, control the nature and pattern of the transition zones between adjacent systems.

These transition zones or *ecotones* [156] have a set of characteristics uniquely defined by space and time scales and by the strength of interaction between adjacent ecosystems (see Section 2.3). Because ecotones usually represent relatively steep gradients in both abiotic and biotic variables, they facilitate the ecological analysis of mechanisms contributing to biodiversity and flow of energy or materials across the landscape [157].

2.2.1. Terrestrial and Lotic Ecotones

In view of the ecological importance of ecotones, they can be divided into three broad classes.

Terrestrial ecotones may be pragmatically defined as discontinuities between systems. Consequently, the most obvious ecotones in terrestrial ecosystem complexes involve transitions between plants of communities dominated by different life forms. Large-scale examples are transitions from tundra to taiga along thermal gradients or transitions from prairie to forest along continental moisture gradients; a frequent small-scale type is the transition from field to woodlot in agricultural landscapes. This pragmatic view of terrestrial ecotones depends highly on the contrast between the different elements contained in the definition of the landscape, and the degree of contrast is necessarily a function of the variables used by the observer to categorize the landscape elements [138], [158]. Thus, a more precise and generally applicable method of defining ecotones is based on areally valid measurements of ecologically relevant parameters and subsequent multivariate cluster analysis. The results are operationally homogeneous spatial units (patches) separated by distinct boundaries whose location and geometry depend on the variables used to characterize the primary measuring points or elementary spatial units, respectively; the fusion level of clustering adopted; and finally the scale selected [159], [160].

Lotic ecotones can be defined, in an analogous way, as fluvial boundaries. This definition indicates that resource patches are separated by both longitudinal (i.e., upstream – downstream) and lateral (landward) ecotones that operate over highly variable temporal and spatial scales. This type of ecotone appears to be highly sensitive to landscape changes caused by physical and biotic disturbances. Examples of direct influences of disturbances are removal of riparian vegetation by floods or landslides, and edaphic or vegetative modifications by animals and, in particular, humans. Indirect influences, such as changes in concentration gradients of dissolved chemical compounds and pathways of chemical reactions,

Figure 20. Ecosystem response to different types of environmental gradients (after [155], modified)
A) Case in which the response of the ecosystem is smooth with respect to the environmental variable; B) Case in which the response is discontinuous; C) Case in which the response is folded and results in hysteresis; D) Case in which the system can have multiple responses

Figure 21. Exchange processes in ecotones of the Bornhöved Lake District, Schleswig-Holstein (after [157], modified)
a.s.l. = above sea level

may result from changes in edaphic and vegetative properties following direct impacts [2], [35], [161], [162].

2.2.2. Lentic and Wetland Ecotones

Lentic ecotones. (i.e., boundaries between water bodies such as lakes, ponds, or reservoirs and adjacent terrestrial patches) also play an important role in coupling ecosystems. With their steep gradients and typically great heterogeneity, lentic ecotones can contribute considerably to mitigating unfavorable changes in aquatic ecosystems. Furthermore, they regulate the landscape mosaic by controlling energy and nutrient flow between adjacent patches in the ecosystems [157], [163].

Wetlands are defined as lands transitional between terrestrial and aquatic ecosystems where the water table is at or near the surface or the land is seasonally covered by shallow water. Therefore they support, at least periodically, hydrophytes, and their substrate is classified predominantly as undrained hydric soil [164]. A clear-cut ecological distinction separates *tidal* and *inland wetlands*, which may be subdivided further [36]. Wetlands have internal and external boundaries separating distinct vegetation patches [165], [166]. They can be categorized into various types according to the flows that dominate in the tidal and inland environments. In both tidal and inland wetlands, vertical and horizontal transfers occur across a series of surficial and lateral boundaries. Flows across *surficial boundaries* (e.g., graded sediment beds or soil horizons) include transfer from aerobic to anaerobic soils, from soils to surficial vegetation and then to litter and vice versa, and from open water to the atmosphere.

Transfers across *lateral boundaries* include material flows from the upland to the wetland (upland – wetland ecotones) or from the wetland into adjacent open water (wetland – open-water ecotones), from groundwater aquifers into soils, or across vegetation patches with each community dominated by different species (wetland – wetland ecotones).

Figures 21 and 22 illustrate a combined lentic – wetland – upland ecotone situation in the Bornhöved Lake District (Schleswig-Holstein). The figures show that lentic ecotones form unusually differentiated habitats [136]. Various microenvironments are formed within the shore zone of the water body, and similar microenvironments occur in certain sections of water bodies contrasting in size, depth, productivity, and catchment area [167]. Lentic ecotones have rich plant and animal communities characterized by a shifting proportion of terrestrial and aquatic organisms.

Allochthonous and autochthonous material is the source of organic matter in ecotonal shore zones: matter originating from primary production by macrophytes and algae and accumulated material of terrestrial origin supplied by the drainage basin. A fast decomposition rate in several ecotonal habitats makes this material available to higher trophic levels much more quickly than in most land and water habitats [136], [163].

The majority of lentic ecotones in densely populated areas of the world is under visible human impact. Lake eutrophication, air pollution, sewage input, agricultural practices, and tourist activities often damage them. Disappearance of terrestrial and aquatic vegetation is the most common response to such unfavorable conditions.

2.3. Sensitivity of Ecosystems and Ecotones

In ecology, the sensitivity of biota or ecosystems to disturbances may be defined in terms of community stability. Questions of persistence and the probability of extinction are of particular importance in this connection; hence, these measures are also frequently defined as aspects of stability. Stability denotes the ability of a system to return to an equilibrium state after a limited disturbance, while persistence is an indication of resilience in the sense defined by Holling [168]: i.e., the capacity to absorb changes of state and driving variables and parameters. The more rapidly a system returns to equilibrium with the least fluctuation, the more stable it is, which means in terms of thermodynamics that stability is coupled with a (relative) minimum of entropy production [2], [169]. Further differentiations lead to various notions of community stability and nondemographic stability measures.

Figure 22. Water balance of ecotones adjacent to Lake Belau, Schleswig-Holstein (after [157], modified)
CR = Capillary rise; GD = Groundwater discharge; GF = Groundwater flow; GR = Groundwater recharge; GRL = Groundwater recharge by lake water; GRW = Groundwater recharge by wetland water; IF = Interflow; IN = Infiltration; OF = Overflow; PW = Ponding water; SE = Seepage on slope; SP = Spring at foot of slope; SR = Surface runoff; WL = Waterlogging

In the light of these definitions, a sensitive ecosystem is one that responds readily to a particular stress; an insensitive ecosystem may be oblivious to the stress. Sensitivity has also a temporal component: a system that responds more rapidly than another is considered more sensitive. Because of the complex character of system sensitivity to stress, various measurable aspects of sensitivity are recognized, which are summarized below:

– *Stability* how an (eco)system responds to perturbation and how readily it recovers
– *Resistance* rate at which (eco)system indicators change in response to a given stress – more resistant systems change more slowly
– *Recovery* how the system responds following removal of the stress. Recovery has two components: how rapidly and how effectively. (The temporal aspect is characterized as the system's resilience.)
– *Resilience* the inverse of the length of time required to return to near normal. According to WESTMAN [170], four components of resilience can be distinguished:
  – *Elasticity:* time required to restore the system to its initial steady state
  – *Amplitude:* zone of deformation from which the system will still return to its initial state
  – *Hysteresis:* extent to which the paths of degradation under chronic disturbance, and of recovery when disturbance ceases, are mirror images of each other
  – *Malleability:* degree to which the new steady state established following recovery differs from the original steady state

Most of the above definitions explicitly or implicitly assume that the system is in a steady state before a stress is applied. This is not necessarily true because ecosystems are generally continuously changing and developing. Therefore, the system need not return to a steady state after recovery, merely to a "near-normal" state.

In some instances the ecosystem can switch with relatively minor disturbances into another steady state. This is called bifurcation: rapid transition at a critical point into a new steady state. Examples of bifurcation of aquatic ecosystems are, for example, the rapid change of lakes from a clean-water state with low amounts of harmless algae to a highly polluted state with highly noxious blue-green algae, or the switching of prairie lakes with healthy fish populations to a state with fish-kills.

2.3.1. Different Notions of Community Stability

A first distinction is between local and global stability. *Local stability* or stability in the vicinity of an equilibrium point describes the tendency of a community to return to its original state when subjected to a minor perturbation. *Global stability* describes this tendency when the community is subjected to a major disturbance. The graphic visualization of solutions to the equations of population dynamics for an *m*-species community may be represented on some *m*-dimensional surface, where each point marks a set of populations. Then, equilibrium situations are in principle characterized by those points at which the surface is flat; by equating the configuration with that of a landscape, in customary geographical notation this means on hilltops and in valley bottoms. The hilltop equilibria, however, are obviously labile (i.e., unable to survive the smallest displacement); only the valley bottoms are stable configurations (see Fig. 23 A). In looking beyond the realm of linearized stability in the immediate neighborhood of equilibrium points for which straightforward mathematical tools exist the situation becomes more complicated. Appropriate representation of the *global stability* of a system implies recourse to nonlinear equations of population biology (see Fig. 23 B). Again in geographical terms, such a global analysis aims at comprehending the stability of an entire landscape, not just the immediate vicinity of equilibrium points. This involves appropriate recognition of the fact that real-world environments are uncertain and stochastic, which means that the corresponding environmental parameters in the model equations exhibit random fluctuations [6], [171], [172].

This leads to a yet more general meaning of stability, termed *structural stability*, which refers to the qualitative effects on solutions of the model equations that are due to gradual variations in the model parameters. Thus, a system may be considered structurally stable if these solutions change in a continuous manner. Conversely, a system is structurally unstable if gradual changes in the system parameters (e.g., alterations in site factors of a community) produce qualitatively discontinuous effects [2], [37], [172].

2.3.2. Biodiversity and Stability of Model Communities

An important issue of theoretical ecology is how biodiversity relates to community structure and which community-level properties emerge from the disparate interactions of organisms, populations, and site qualities. Possible examples of such "emergent properties" include trophic and guild structures, stability, resilience, and successional stages. A generalized offshoot of the concept of emergent properties is the notion that biological systems are hierarchically organized, with new properties at each level of the hierarchy [11], [38], [173]. According to this view, diversity is better understood if ecosystems or biota are decomposed hierarchically so that each process can be viewed as a stabilizing or disruptive factor at each level in a hierarchy of time and space scales.

During the 1950s and 1960s, the "conventional wisdom" in ecology [6] was that increased complexity within or diversity of a community lead to increased stability [39], [174]. May [175], however, came to contrasting conclusions by means of model food webs comprising a numberof interacting species. The term β_{ij} was used to measure the effect of species *j* 's density on species *i*'s rate of increase. Thus β_{ij} would be zero when there was no effect, whereas both β_{ij} and β_{ji} would be negative for two competing species, and β_{ij} would be positive and β_{ji} negative for a predator (*i*) and its prey (*j*). Setting all self-regulatory terms (β_{ii}, β_{jj}) in his randomly connected networks at -1, May distributed all other β-values at random, including a certain number of zeros. Thus, the cybernetic webs serving as ecosystem models could be described by

Figure 23. A) Visualization of system dynamics and stability conditions, equating phase – space characteristics with a landscape – labile equilibria (i.e., both low local and global stability); B) Illustration of global stability conditions by means of a landscape configuration, indicating different states of low local, but generally high stability

three parameters: S, the number of species; C, the connectance of the web, i.e., the fraction of all possible pairs of species interacting directly ($\beta_{ij} \neq 0$); and β, the average interaction strength, i.e., the average of nonzero β-values, regardless of sign.

Comparative analysis of these networks showed that they were likely to be stable (i.e., the populations represented would return to equilibrium after a small disturbance) only if

$$\beta\,(SC)^{1/2} < 1 \tag{25}$$

In other words, MAY's model suggests, like others, that "too rich a web connectance or too large an average interaction strength leads to instability. The larger the number of species, the more pronounced the effect." This inference is clearly in contradiction to the above conventional wisdom, but it indicates that no general, unavoidable connection exists between complexity or diversity, respectively, and community stability. Another question is, how much is MAY's result an artifact arising from particular characteristics of the model and the interpretative techniques applied [6], [37].

Figure 24. Species-deletion stability plotted against interspecific connectance (after [6])

The picture also alters if, instead of focusing on local stability and correspondingly minor disturbances, larger perturbations are considered or "species-deletion stability," which is particularly interesting from an ecotoxicological point of view. Under the assumption of the deletion of one species of a community owing to a persistent impact, the system is said to be species-deletion stable if all of the remaining species are retained at locally stable equilibria. In the simple six-species community of Figure 24 containing two top and two intermediate predators and two basal species (either plants or categories of dead organic matter), interaction strengths were defined at random, while connectance was varied systematically; thus, complexity could be equated with connectance. Again, stability generally decreased with increasing diversity, but this trend was reversed when basal species or elements were eliminated. However, within the simulated small subset of stable communities, resilience actually increased with complexity.

Other theoretical approaches to the stability problem are due to MCMURTRIE [176], PIMM [10], and ULANOWICZ [40], who established criteria for the stability of ecosystems under certain restrictive conditions, such as zero-sum games. In particular, they have shown that ecosystems can become unstable against weak perturbations when the complexity increases beyond a certain value, although the transition is not always sharp [177].

BACHAS and HUBERMAN [178] related the complexity of hierarchical structures, as measured by their diversity [179], to dynamical behavior. The result suggests that there might be a quantifiable relation between the diversity of a hierarchical structure and its stability. Furthermore, the results of DOREIAN [180] and of BRIAND and COHEN [181] suggest that the effective dimensionality of the space in which the interactions occur, and the overlaps in food webs, contribute to the nature of the structural representation of the community. Hence, it may be concluded that their stability will likewise be affected, which is in agreement with the results of a comparative model analysis of unstructured cooperative interactions between arbitrary species on the one hand and ecosystems with pyramidal organization on the other [182].

In returning to the original problem set out by MAY [175], this author derived a condition of stability for more general systems as a function of species diversity and the strength of interactions. The stability of such systems is determined by the behavior of the largest eigenvalue of matrices governing the response of the system to small perturbations. As a result, MAY and

coworkers showed in the case of nonhierarchical organizations how the removal of a zero-sum game condition can lead to further reduction of stability. Examining hierarchical ecologies, they demonstrated that these hierarchical structures are intrinsically more stable than unstructured ones [182].

The conflicting results among models developed so far must be considered in the light of model structure, particularly the number and composition of elements (i.e., species) simulated. In comparison to real communities with hundreds or thousands of species [136] and highly variable degrees of interaction, most models are extremely "impoverished" in species. Furthermore, the models quite often refer to randomly constructed communities, whereas real communities and ecosystems are far from being randomly constructed and normally display a complex hierarchical structure [2], [173]. Unstable communities are liable to collapse when they experience environmental conditions that reveal their instability, but the range and predictability of conditions may vary markedly from place to place. Under stable and predictable site conditions, a community will experience only limited fluctuations; thus, even a dynamically fragile one may still persist. By contrast, in a variable and largely unpredictable environment, only dynamically robust communities are likely to persist.

2.3.3. Stability-Oriented Biodiversity Analyses of Real Communities

Following MAY's approach, studies have been performed on the general importance of dynamic stability constraints by examining the relationship among S, C, and β in real communites. It follows from the inequality of Equation (25) that increases in S will lead to decreased stability unless compensatory decreases occur in C or β. Since data on interaction strengths for entire communities are unavailable, β is usually assumed to be constant. In such a case, communities with more species would retain stability only with a corresponding decline in average connectance, which means that the product SC should remain approximately constant.

REJMANEK and STARY [183] studied geographically distinct plant – aphid – parasitoid communities in Central Europe and found a decrease of C with an increase in S, with SC lying between 2 and 6. Evaluating the literature, BRIAND [184] analyzed 40 terrestrial, freshwater, and marine food webs and calculated a single value for connectance on the basis of both predator – prey and presumed competitive interactions (i.e., $C_{\max}$). Once again, connectance decreased in an approximately hyperbolic way with species number, and SC was about 7.

MCNAUGHTON's field test [185] of MAY's inference, carried out in 17 grassland stands in Tanzania's Serengeti National Park, showed that "both average interaction strength and connectance declined as species richness of the grassland increased. The correlation was somewhat stronger for interaction strength than for connectance." Hence, if the grassland communities analyzed are representative biocenoses, species-poor stands are likely to be characterized by strong interactions among species, while species interacting with many others do so relatively weakly. Diffuse competition obviously increases with the number of species; in addition, MCNAUGHTON's findings suggest that communities have a blocklike or patchy organization consisting of species interacting among themselves but only little with species in other blocks.

Table 7. Influence of nutrient addition on species richness, equitability (H/ln S), and diversity in two fields; and influence of grazing by African buffalo on species diversity of two vegetation plots (after [185])

	Control plots	Experimental plots	Statistical significance
Nutrient addition			
Species richness per $0.5\,m^2$ plot			
Species-poor plot	20.8	22.5	n.s.∗
Species-rich plot	31.0	30.8	n.s.∗
Equitability			
Species-poor plot	0.660	0.615	n.s.∗
Species-rich plot	0.793	0.740	$p < .05$
Diversity			
Species-poor plot	2.001	1.915	n.s.∗
Species-rich plot	2.722	2.532	$p < .05$
Grazing			
Species diversity			
Species-poor plot	1.069	1.357	n.s.∗
Species-rich plot	1.783	1.302	$p < .005$

∗ n.s.=not significant.

McNaughton [185] also tested the prediction that complex communities are less likely to return to their state prior to perturbation. In the first experiment, the perturbation resulted from addition of plant nutrients; in the second, it involved the action of grazing buffalo. The results summarized in Table 7 indicate that each perturbation significantly reduced the diversity of the species-rich but not the species-poor community.

According to these analyses and studies on the species diversity of tropical rain forest ecosystems in particular, a climax community is more likely to have both low fluctuations in composition (i.e., high stability) and low resilience as the homogeneity of its environment in space and time increases. Figure 25 summarizes the diversity and abundance spectra of numerous neo- and paleotropical rain forest communities as related to soil properties [2]. The diagram clearly shows that in most cases, rain forest stands on highly nutrient-depleted ferralsols, acrisols, and podzols of tropical lowlands attain diversity indices greater than 90 % of the theoretical maximum. However, a further differentiation according to local nutrient status and water budget is not possible with the data available. Nevertheless, stand 38 (Borneo) is of particular interest since it is representative of a forest that developed on a tropical bog; its exceptionally low index value allows the conjecture that its nutrient supply has fallen below a critical value, which is discussed in a broader thermodynamic context in Section 2.3.7.

In terms of May's stability criterion (Eq. 25), these findings would indicate a very low degree of connectance and average interaction strength between plants of the same species. With regard to nutrient uptake from the soil, this means a well-balanced low-grade intra- and interspecific competition involving a marked selection of K strategies (i.e., care for the offspring in the widest sense) and the formation of numerous ecological niches. Therefore, highly complex rain forest communities with their relatively constant environments appear to be more susceptible to outside, unnatural disturbances than the simpler, more robust communities of ectropical regions.

The example of Vietnam's inland forests is illuminating in this respect, since they still bear the scars of a ten-year herbicide spraying program by the U.S. Air Force during the Vietnam war. According to official U.S. figures, some 10.3 % of these forests, in addition to 36.1 % of mangrove forests, 3 % of cultivated land, and 5 % of other land, were sprayed. Thus, some 90 000 t of herbicides and antiplant chemicals was used between 1962 and 1971 [186]. Most of the spraying was with Agent Orange [i.e., a 1 : 1 mixture of (2,4-dichlorophenoxy)acetic acid (2,4-D) and (2,4,5-trichlorophenoxy)acetic acid (2,4,5-T)]; Agent White (2,4-D and picloram); and Agent Blue (cacodylic acid). Some 20 years after the spraying ended, little regrowth had occurred in areas sprayed three or four times. The fertility of the soils is rapidly reduced further if forests are replaced with grassland or bamboo, as has happened in a large part of the sprayed region. In particular, a loss of minerals and nitrogen has occurred, and in some cases a decrease in soil pH, which all inhibit diversified recolonization.

Defoliation has clearly affected the faunal assemblages, not only in the areas totally defoliated and subsequently converted into grassland but also in those regions less frequently sprayed where the plants in the upper reaches of the forest were damaged. In both areas, the number of animals and birds has dropped dramatically, and animals are also at considerable risk in some of the forest areas that have been isolated from the main body by herbicide application. Furthermore, the concern is that Agent Orange contained a high concentration of the highly toxic contaminant 2,3,7,8-tetrachlorodibenzo-*p*-dioxin, which is both teratogenic and carcinogenic in animals, and toxic to humans as well.

In comparison to tropical lowland rain forests where species diversity and nutrient content of the soil are negatively correlated, the situation in temperate regions is different. The composition of 132 plant communities from all parts of the continental United States (except Alaska) evaluated in relation to climate and soils shows that the amount of water available for evapotranspiration is of decisive importance for species diversity. This is further corroborated by the highly significant correlation between diversity and the temporal distribution of rainfall. Conversely, the analysis of 194 plant communities in northern Germany led to the conclusion that, most frequently, high diversity coupled with medium to low proportional abundances occurs on sites

Figure 25. Diversity and abundance spectra of neo- and paleotropical rain forest communities

with high nutrient supply and medium to low soil moisture, whereas the combination of both high diversity and high abundance with high nutrient and medium to low moisture status is comparatively rare. These inverse diversity –nutrient relationships in tropical and ectropical environments, on the one hand, and the fact that soil moisture controls diversity in the United States but not in northern Germany, on the other, lead to the final question of whether a unifying interpretation of these apparently incoherent results is possible. This is given in Section 2.3.7 by considering ecological communities as dissipative structures.

2.3.4. Nondemographic Measures of Stability

The introductory remarks on stability and resilience indicate that community and ecosystem stability can be viewed from perspectives other than demographic ones. The highly different aspects of functioning (e.g., primary productivity, nutrient cycles, energy and water balance) and the composite aspects of structure such as standing-crop biomass appear to be particularly important [6].

McNaughtons's [185] studies on Serengeti grassland communities showed that species-rich associations responded to perturbations with a significant drop in species diversity, while species-poor communities did not. In terms of *primary productivity*, however, grazing as a natural perturbation reduced the standing-crop biomass in the species-poor grassland much more than that of species-rich communities. Similarly, several studies have revealed a marked influence of *food web* structure on community resilience in response to perturbations of energy and nutrient supplies. O'Neill [187] considered a three-compartment system consisting of active (photoautotrophic) plant tissue, heterotrophs, and dead organic matter, and found that the rate of change in standing crop depends on the energy transfer among these compartments. With regard to the autotrophic compartments, it depends on the input variable (net primary productivity) and two output variables (fraction consumed by heterotrophs and fractions lost to soil by litterfall) in addition to a great variety of translocation processes [85]. The rate of change of the heterotrophic compartment depends on two inputs (consumption of living plant biomass and dead organic matter) and two outputs (respiratory heat loss and defecation). Finally, as Figure 26 shows, the energetic exchange rate of soil organic matter depends on two inputs (litterfall and defecation) and two outputs (physical transport into neighboring ecosystems and consumption by heterotrophs).

On the basis of this simple configuration, and inserting real data from communities representing a pond, a spring and tundra, tropical forest, a temperate deciduous forest, and a salt marsh, O'Neill [187] subjected the models of these communities to a standard perturbation that consisted of a 10 % decrease in the initial standing-crop vegetation. The rates of recovery toward equilibrium thus monitored and plotted as a function of the *energy input* per unit standing crop of living tissue are presented in Figure 27. It shows that the flux of energy through the different subsystems has an important influence on community resilience; the higher the flux is per unit standing crop, the more quickly will the effects of perturbation be compensated. This, in turn, seems to depend in part on the relative importance of heterotrophs in the system considered. The pond as the most resilient system has a heterotrophic biomass 5.4 times that of autotrophs, reflecting the high turnover rate of phytoplankton; the least resilient tundra has a heterotroph : autotroph ratio of only 0.004. De Angelis [188] has come to analogous conclusions in terms of residence times of various nutrients in different compartments of woodland communities. Thus, a unit of nitrogen exists in soil for an average of 109 years, is taken into forest biomass for 88 years, remains in the litter for up to 5 years, and passes through the detrivore compartment in a few days. In contrast to nitrogen, calcium is a less tightly cycled element whose residence times in soil and biomass amount to only 32 and 8 years, respectively.

More detailed long-term investigations in the forest and agroecosystems of the Bornhöved study area (Schleswig-Holstein, Germany) corroborate these findings. Here, the nitrogen deposition amounted to 19.9 and 18.2 kg ha^{-1} a^{-1} in 1989 and 1990, respectively, with an ammonia fraction of 47 % (60 %) and 23 % (7 %) of organic nitrogen-compounds, while nitrate deposition yielded 6.1 and 5.9 kg nitrogen per hectare

Figure 26. Three-compartment model of an ecosystem with typical energy transfers (after [187], modified)

Figure 27. Recovery rate as an index of resilience after perturbation as a function of energy input per unit standing crop (after [187])

and year, respectively. The nitrogen balance of a field is summarized in Table 8.

Table 8. Nitrogen balance of a field in the Bornhöved Lake District

Process	Amount of nitrogen (measured, kg ha^{-1} a^{-1})	
	1989	1990
Initial N content	51 [a]	38
Total N input	384	222
NO_3-N	30	14
NH_4-N	118	64
N_{org}	236	144.5
Mineralization	221 [b]	215 [b]
Nitrification		
Plant uptake	206	121
N×leakage	110	129
Other N losses [c]	7	7
Residual N_{min} content	39	4.5
Balance	+59	+70

[a] Deduced value. [b] Net mineralization. [c] Denitrification and volatilization of ammonia.

The wet deposition of nitrates via canopy flow in a neighboring beech stand (*Asperulo–Fagetum*) of relatively uniform age structure (95 years) amounted to 30.3 kg nitrogen per hectare and year in 1989 and 37.5 kg in 1990, again with a major ammonia fraction. Comparably high were the deposition rates to the soils of a neighboring alder stand (*Carici elongatae–Alnetum*), where additional nitrogen fixation is due to the symbiotic activity of *Frankia*.

With regard to internal nitrogen fluxes the beech and alder stands differ considerably. In the first case, litterfall transported 78 kg nitrogen per hectare and year to the soil surface, where the chemical and microbial transformation processes induce seasonal changes in N_{min} content as illustrated by Figure 28. In the light of the site characteristics of this stand (Dystric Cambisol), the figures are indicative of rather limited nitrogen export from the community, which is further corroborated by measurements of the nitrogen fluxes in the related seepage water. In the distinctly more resilient alder stand, the nitrogen input due to litterfall amounted to 109.4 kg ha^{-1} a^{-1} in 1989 and 104.5 kg ha^{-1} a^{-1} in 1990, respectively. In comparison to the above beech stand, microbial degradation of the litter is very high in the *Alnetum*, and within 18 months almost all of the leaf tissue is degraded., Chap. 1.

2.3.5. Sensitivity of Aquatic Ecosystems

Aquatic ecosystems are natural collectors of materials from their surroundings, and water washes matter out from the land surface. Human activities increase this natural washout enormously by destroying the natural vegetation cover of the landscape due to agricultural, mining, construction, and forest-cutting activities. For organic matter of natural origin, with its contents of nutrients necessary for further growth of vegetation, a relatively closed cycle originally existed: the remains of organic matter consumed by humans and their domestic animals were returned to fields. In medieval times, increasing population concentrations in towns created local accumulations of decaying organic matter leading to the spread of infectious diseases. This problem consequently was solved by disruption of the feedback cycle. Organics with their content of elements essential for life were directed to streams, rivers, lakes, and ultimately the sea. The result was continuous deprivation of nutrients in soil and a need to subsidize them to maintain and enhance agricultural productivity. The open flow of nutrients from soil and deeper earth layers started to create unpleasant conditions by increasing aquatic production not only in streams, lakes, and ponds but also in the greatest lakes of the world and marginal seas such as the Adriatic. In addition, humans pollute water by applying various chemicals to the environment – both at home and in industry – and by extracting materials from the earth and transporting them over large distances, in part by means of waterways. Tanker catastrophes are becoming more and more common, and road transport is no less hazardous to waters.

Pollution sources are usually classified in two categories: point and nonpoint sources. Although *point sources* coming from a factory or town are technically much easier to handle, *nonpoint* sources are not only difficult to detect but still more difficult to eradicate. Typical nonpoint pollution sources originate from fertilizers and other chemicals spread on fields. Another source of water pollution is deposition of airborne pollutants, some of which reach water bodies in remote regions. The findings of elevated concentrations of DDT in Antarctica show the global scale of pollution problems.

Figure 28. Seasonal variation of the N_{min} content of beech litter of a Schleswig-Holstein *Asperulo – Fagetum* stand in 1989 and 1990
Ah-horizon = part of the surface soil (→ Soil)

The sensitivity of aquatic ecosystems to disturbances differs depending on the type and size of the respective ecosystem and the nature of the disturbance. In scientific terminology, all disturbing factors are stressors and the term "sensitivity to stress" is used. Stress is usually defined as a measurable alteration of the state of organisms as induced by an environmental change that renders the individual, population, or community more vulnerable to further environmental change.

2.3.5.1. Reactions of Aquatic Ecosystems to Stress

Aquatic ecosystems under stress undergo both changes of structure and changes of function. *Changes of structure* are manifest by changes in the composition of populations of different species in the ecosystem. *Changes of function* are represented by differences in the organic matter productivity of the respective ecosystem and in the rates of release and utilization of different gases and minerals. Thus, both a sensitivity of ecosystem structure and a sensitivity of ecosystem function occur. No uniformity of

opinion exists as to whether the structure or function of ecosystems in general is more sensitive to various stressors. Several researchers feel that functional variables, especially those that are substrate limited, will always be less sensitive than structural measures because of functional redundance in the community. They suggest that any loss of functional capacity by one organism is immediately compensated by increased activity of another organism. Other scientists feel that functional capacity can be affected before compensatory mechanisms operate. This is especially likely when the compensatory mechanisms themselves are adversely affected by the stress or when they operate on a more lengthy time scale relative to the functional measure [189]. These authors have also summarized various functional reactions of ecosystems:

1) Community respiration increases
2) Productivity – respiration ratio becomes unbalanced
3) Productivity – biomass ratio increases as energy is diverted from growth and reproduction into acclimation and compensation
4) Importance of auxiliary energy increases (import becomes necessary)
5) Export of primary productivity increases
6) Nutrient turnover and nutrient loss increase
7) One-way transport increases and internal cycling decreases
8) Life span decreases; turnover of organisms increases
9) Trophic dynamics shift, food chains shorten, and functional diversity declines
10) Efficiency of resource use decreases
11) Condition declines

A well-documented example of greater sensitivity of functional variables of a terrestrial ecosystem is presented by Van Voris et al. [190], who measured structural and functional changes in small patches of a meadow subjected experimentally to cadmium stress. Functional changes such as spectral complexity and calcium export were affected at concentrations that did not affect structural measures such as the presence or absence of certain species.

In the direction of slowly and rapidly reacting ecosystems at opposite ends of the scale are pelagic lake and reservoir communities composed of very short-living (few hours to few days) species that react to any stress by their rapid appearance or disappearance, and forests with very long-living tree species that are incapable of rapid presence – absence types of reaction. Benthic communities of rivers and fish populations are intermediate: their life span is measured in months to years.

In aquatic ecosystems, many reports have shown greater relative sensitivity of structural than functional variables. For example, during his extensive comparative studies of Canadian Shield lakes, Schindler [191] found no significant changes in decomposition or nutrient cycling in whole lakes treated with acid, but species composition of phytoplankton was among the earliest indicators of change. Crossey et al. [192] found in impaired rivers that measures of production and respiration were more variable than the macroinvertebrate composition. Crumby et al. [193] studied the biological reaction of Roaring River in north-central Tennessee to stress caused by construction around the river and by inadequate agricultural practices in the watershed. Species composition changes were reflected in a general decline in numbers of intolerant species and simultaneous increase of tolerant species.

However, many reports of the greater sensitivity of functional variables of aquatic ecosystems also exist. Rodgers et al. [194] found that process rate changes were more sensitive than biomass or chlorophyll concentration in detecting the effects of diverse chemicals on periphyton in artificial streams. When dealing with enrichment, functional measures are often a good warning indicator. Uhlmann et al. [195] and Gnauck [196] summarized structural and functional changes in aquatic ecosystems and gave examples of experiments equivalent to those of Van Voris et al. [190]. Figure 29 compares the degree of variability (expressed by a relative index of instability) during a 50-d experiment with an experimental purification pond for several structural and a few functional variables. The greatest instability equivalent to the highest sensitivity is observed (with the exception of the alga *Scenedesmus obliquus*) for the biomass of individual species of organisms (index values between 0.85 and 1.45), while functional variables such as oxygen concentration, primary production, and turbidity and the summarizing biomass of functional groups of organisms such as zooplankton or phytoplankton or chlorophyll-

a levels have an index close to or below 0.5. The least sensitive appeared to be the organic carbon elimination capacity of the pond, which characterizes, from the human point of view, its most important function.

Once the stress has ceased, two possibilities exist:

1) Reversible changes are induced
2) The changes prove irreversible

The deforestation in the coastal hills of Venezuela is a drastic example of irreversible changes of an extensive ecosystem. The soil structure, seed sources, and local physical environment have changed to such a degree that forests have not returned even after the areas were abandoned by humans. Perhaps the example merely reflects an exceedingly long recovery period, and the system will eventually recover. Yet for practical purposes, these ecosystem changes are permanent. A dried lake and a watershed with homogeneously distributed amounts of toxic substances are examples of irreversible changes of aquatic ecosystems.

If the disturbance is sufficiently regular and of near-natural origin, components of the ecosystem may adapt and eventually require disturbance to maintain a normal, resilient system (tidal pools require daily exchange with the sea, pastures require mowing or grazing, many forests are adapted to periodic fires). In aquatic ecosystems, this system of reaction is seen in periodic pools, which are inhabited by animals adapted to desiccation. Their characteristic fauna will disappear when water is permanently present because they are inferior in competition with longer-lived species not needing desiccation.

For chemical stress, the recovery of aquatic ecosystems depends mainly on the degree of accumulation of the respective chemical in the environment and the rate of flow. This conclusion can be corroborated by comparing the findings in lakes with those in rivers. The recovery of eutrophic or highly polluted lakes after the sources of organic pollution and phosphorus causing lake eutrophication have been reduced is very slow. Recovery takes as much as ten to twelve years. The delayed reaction is due to the enormous quantities of decomposable organic matter and phosphorus stored in the bottom mud. Oxygen at the bottom is consumed during the decomposition of organic matter and, under such conditions, phosphorus is continuously released. This phenomenon is called internal P load, which indicates that when the external load ceases, an internal one plays a major role in continuing eutrophication. At the other end of the spectrum are rivers with high flushing. Yount et al. [197] made an overview of the recovery of rivers after a stress and found that almost full recovery may occur within about two years.

2.3.5.2. Sensitivity to Different Stressors

The sensitivity of marine and freshwater fish worldwide to recent changes in the environment was determined by means of changed species diversity [41]. The numbers of extinct, endangered, or threatened species and species of special concern represent 21 – 69 % of the total fauna in different regions of the world, with the exception of only 9 % in Latin America. The highest numbers were found in California and South Africa; low figures in Iran, Australia, Sri Lanka, and also Arkansas. Major causes of this situation are the extraction of water for various human uses, physical alteration of fish habitats (mainly by channelization, construction of weirs and reservoirs, siltation from mass erosion and degradation of wetlands), and pollution (mainly municipal and industrial point-source pollution, agricultural pollution, and acid rain). The sensitivity of aquatic ecosystems to different specific stressors depends on the type of ecosystem and the agent. For chemical agents the degree of interference with the structure and metabolism of organisms is important. However, even such components as structural macroelements of organisms may be harmful, once their concentrations in the environment exceed certain levels. This is the case, for example, with plant nutrients. When present in large excess, they decrease life functions (e.g., plant growth; see Section 2.1.4.3). Sensitivity to toxic chemicals is discussed in Section 2.4. Sensitivity to acidification as an environmental process is described in Section 2.3.5.3 together with other signs of global change.

The sensitivity of aquatic ecosystems to *ionizing radiation* is not well known. However, some reactions parallel to those observed for terrestrial ecosystems are expected to be valid.

Figure 29. Comparison of the degree of variability, expressed in terms of an instability index, during a 50-d experiment with an artificial purification pond (after [195], modified)

The latter were studied in detail by WOODWELL [198]. He demonstrated that in a mixed forest – shrub – grassland exposed to different levels of ionizing radiation, the diversity of species is more sensitive than organic production. The sensitivity increases with the size of the organisms. The reason is that increased size puts greater demand on the photosynthetic mechanism for maintenance, leaving less for growth and repair. Sorting of the sensitivity was also observed on the basis of chromosome size: plants with large chromosomes were more sensitive.

Sensitivity to *communal organic pollution* is well known for both stream and lake ecosystems; this is the classical type of pollution studied by quantitative methods since the beginning of this century, the methods being continuously improved and new methods being continuously developed. From the pollution point of view, organic matter is not characterized as a chemical species but in a summarizing way, namely, the

total of easily decomposable or refractory matter. The difference between the two categories is arbitrary: easily degradable matter is decomposed by the natural population of microorganisms within five days' incubation. In streams, systematic changes of the composition of benthos are observed with certain amounts of organic pollution. This is the basis for the bioindicator approach to detect the degree of organic pollution. However, geographic differences in the benthic fauna of different regions; dependence on stream characteristics such as size, rate of flow, and bottom type; and combination of pollution types all complicate the evaluation.

2.3.5.3. Sensitivity to "Global Change"

One of the effects anticipated by part of the scientific community to cause major changes in world climate and consequently local weather and food production within the next decades is "global change." Since the 1940s, compounds such as CO_2, chlorofluorocarbons (CCl_2F_2 and CCl_3F), methane (CH_4), and dinitrogen monoxide (N_2O) have displayed notable and deleterious increases or decreases in the case of tropospheric ozone (O_3). These gases (except O_3) are classified as "greenhouse gases" because they have a greenhouse effect on earth's atmosphere.

About a hundred years ago, CO_2 values of 280 ppm (mL/m^3) were measured in the atmosphere; (in the 1990s), concentrations are about 25 % higher. Carbon is both fixed and released by oceans, biota, and human activities. Approximately 30 % of the global annual carbon fixation by plants occurs in the seas, which also form an integral part of the nitrogen flux of the earth. An estimate for 1980 gave the following figures for the fluxes of carbon among atmosphere, ocean, biosphere, and human activities [199]: 78×10^{12} kg C per year (flux ocean $\leftrightarrow$ atmosphere), 65×10^{12} kg C (flux biosphere $\leftrightarrow$ atmosphere), and 5×10^{12} kg C (flux due to human activities, mainly burning of fossil fuels and land clearance $\leftrightarrow$ atmosphere). Although the contribution by human activities is far less than the natural fluxes, it shifts the total balance significantly.

In the United States, the sources of CO_2 from human activities were estimated for 1987 as follows [42]: 11 % residential, 24 % industry, 30 % transportation, and 35 % electric and power generation. Industry is therefore an important CO_2 source, even when the significant portions of electric power generation and transport associated with industry are neglected.

The climate has changed throughout the last few thousand years due to natural causes; the influence of human activities superimposed on these variations has also contributed significantly. Scientific documentation demonstrates that the overall rise in CO_2 has already had marked effects on the biosphere. Comparison of different recent plants with herbarium specimens collected many years ago disclosed that the leaf area and the nitrogen content of leaves in 15 species of trees, shrubs, and herbs decreased over the last 240 years. Also, a systematic increase in the growth rate of bristlecone pines and a decrease in stomatal density of the leaves of plants over the last 200 years was observed [200]. Although no aquatic plants were included in the studies, they are expected to be subject to similar effects. The reported changes may seem unimportant; however, this may be only the easily observable tip of the iceberg. More relevant parameters cannot be compared with those of earlier times when no scientific measurements existed. The detection of changes increases the credibility of predictions by demonstrating that biological changes have already taken place and are not merely scientists' anticipation.

Despite many uncertainties in predictions, a certain consensus exists among part of the scientific community that the increase in CO_2 and the other greenhouse gases due to human activities will warm the climate by the middle of the next century between 1 and 5 °C ("global warming"). Greater temperature increases are expected at high latitudes, especially in winter, with consequences for ice melting and sea-level rise. Consensus also exists that changes of this magnitude in temperature will be accompanied by substantial regional anomalies in temperature, rainfall, evaporation, cloudiness, windiness, drought, and so forth that could have substantial impact on agriculture, water supply, human and animal health, biological diversity, energy demand, and sea level [199], [201].

The changes expected in aquatic environments due to these increasing quantities of greenhouse gases are of both a physical and a chemical nature. Physical changes mainly in-

volve global warming and an increased level of ultraviolet radiation at the earth's surface. Ultraviolet radiation in its present spectral composition is readily adsorbed in water, and only organisms living in the uppermost (few centimeters) water layers can be damaged. However, alterations in spectral composition of ultraviolet radiation expected as a consequence of global changes can markedly increase the layers affected.

One indirect effect of global warming on streams is expected in connection with increased variability in stream flow, associated with increased rates of sediment transport and sedimentation. Sediments are expected to fill in some pools and generally cover surfaces. However, streams may be flushed of material periodically. These conditions would favor invertebrates with shorter life cycles adapted to softer sediments, while larger invertebrates could be adversely affected by these conditions because they graze rock surfaces [43].

Indirect effects on aquatic ecosystems are also expected due to the high sensitivity of forest ecosystems to environmental variables. The sensitivity of forests to climate changes was estimated from changes observed during the geological past and from some geographical dependencies observed more recently [202]. The results indicate that during global change, shifts will occur in the geographical ranges of tree species, along with changes in forest productivity. Because of the interrelation of soil nutrients, soil moisture, groundwater, and tree growth, changes in forest ecosystems will have major consequences for aquatic ecosystems, primarily rivers. River flow will be changed and, with it, leaching of minerals and organics from soil will occur to varying extents, with consequences for river inhabitants [44]. Additional indirect effects will be caused by changes in agricultural production.

The probable effect of the expected climate warming on fish of the Great Lakes Basin was estimated by Meisner et al. [203]. They concluded that no full extirpation of species is to be expected, but the populations of the most valued fish, salmonids and coregonids, will decrease, whereas the species less valued by fishermen (cyprinids, esocids, centarchids, and ictalurids) will probably increase. Thus, a decrease of fishery yields of preferred species is expected.

Other global changes in aquatic ecosystems are already observed locally in acidified regions. They result from direct and indirect chemical effects caused by increasing CO_2 levels. Doubling of atmospheric CO_2 levels, which is expected to occur at the beginning of the next century, is supposed to decrease the pH of rainwater by about 0.4 unit, which means a pH drop in some localities to 4.0. The lower pH will increase the solubility of carbonate minerals and increase the calcium, magnesium, bicarbonate, and sulfate content of rivers draining carbonate terrain. The greatest secondary effects on organisms are caused by the increased solubility of aluminum at low pH. Aluminum would be released, predominantly in bedrock terrain. The speciation of aluminum in river water is important in determining the toxicity of elevated aluminum levels as well as the acidity of soil solutions. Inorganically complexed or free aluminum is more toxic than organically complexed aluminum. Lakes with present pH levels of 6.5 are expected to become acidified to pH <5, with considerable effects on inhabiting organisms. Major impoverishment of lakes due to acidification has already occurred in northern Europe and Canada, and in mountainous lakes of more southern localities [45].

2.3.6. Sensitivity of Ecotones

Like communities and ecosystems, ecotones also differ in physical stability or resistance to changes (resilience) caused by disturbances. In contrast to lotic ecotones, adjacent terrestrial ecosystems and ecotones may be viewed as occupying distinctly more stable positions in a landscape where natural disturbances due to geomorphic processes are less frequent than the time for patch adjustment to them (see Sections 2.3.5 and 2.3.7).

In distinguishing reactions, recovery and persistence phases, and recurrence intervals as characteristic parameters of system response to physical disturbance [46], the recovery and disturbance recurrence intervals are of particular ecological importance. The ratio of the recovery to disturbance recurrence intervals R/D suggests differences in recovery or sensitivity characteristics of both ecotones and ecosystems. For unstable systems, the R/D ratios exceed 1. Typically,

this is the case for predominantly transient systems such as many *lotic ecotones* [162]. Normally, deposition and erosion interact with riparian vegetation at varying intensities and frequencies so that communities are kept in the early stages of succession. A decrease in seasonal flooding of the riparian vegetation results in changes via several possible successional pathways, which may lead to the formation of purely terrestrial communities when the system is no longer influenced by flooding.

Examples of this type support the assertion of NAIMAN et al. [155] that a paradox of modeling interfaces is predicting when and where ecotone parameters become unpredictable relative to adjacent homogeneous sites. Chaos theory may be useful in dealing with this uncertainty because ecotones are not simple averages of adjacent systems; the spatiotemporal pattern of environmental factors and the interactions between patches are as important in determining ecotone dynamics on different scales as are the characteristics of adjacent patches.

2.3.7. Stability and Resilience of Ecosystems in Evolution

On a very general level, the apparently unusual – because inverse – relationship between the nutrient status of soil and the diversity of related tropical rain forest communities described in Section 2.3.3 may be interpreted in terms of biological thermodynamics [169]. Biotic communities are open systems in exchange of energy and matter with their environment; their entropy production dS thus comprises the terms $\mathrm{d_i}S$ and $\mathrm{d_e}S$, where $\mathrm{d_i}S$ denotes the entropy production within the system while $\mathrm{d_e}S$ is a flux term describing entropy "export" into the environment:

$$dS = \mathrm{d_i}S + \mathrm{d_e}S \tag{26}$$

The term $\mathrm{d_i}S$ can only be >0, but $\mathrm{d_e}S$ can also be negative. By identifying entropy with disorder, Equation (26) shows that an isolated system can evolve only toward greater disorder. For an open system, however, the "competition" between $\mathrm{d_e}S$ and $\mathrm{d_i}S$ permits the system, subject to certain boundary conditions, to adopt new states or structures. These are stationary if

$$dS = 0 \tag{27}$$

or

$$d_e S = -\mathrm{d_i}S < 0 \tag{28}$$

$\mathrm{d_i}S$ can be expressed in terms of thermodynamic "forces" X_i, and rates of irreversible phenomena J_i [165]; X_i may be gradients of temperature or concentration; the corresponding "rates" are then heat flux and chemical reaction rate. Hence,

$$\frac{d_i S}{\mathrm{d}t} = \sum_{i=1}^{n} J_i X_i \tag{29}$$

Around equilibrium, the relationship between fluxes and forces is linear

$$J_i = \sum_{j=1}^{m} L_{ij} X_j \tag{30}$$

where L_i represents specific coefficients (e.g., coefficients of thermal conductivity or diffusion).

Provided the reservoirs of energy and matter in the environment of the open system are sufficiently large to remain essentially unchanged, the system can tend to a nonequilibrium stationary state far beyond the domain of linear thermodynamics. This state may be associated with dissipative structures [204] (i.e., structures resulting from a dissipation of energy rather than from conservative molecular forces). In considering phytocenoses from the viewpoint of stationary dissipative structures, the relationship of $\mathrm{d_i}S$ and $\mathrm{d_e}S$ as expressed in Equation (28) and the specific boundary conditions controlling entropy production and flux rates appear to be particularly important. A consequence of Equation (28) is that, thermodynamically speaking, stability or the capacity to maintain a nonequilibrium steady state is coupled with a (relative) minimum of total entropy production dS. Clearly this can be accomplished by either minimizing $\mathrm{d_i}S$ or maximizing $\mathrm{d_e}S$ or by a combination of both strategies.

Concentration processes involved in the normal metabolic activities of living systems play an important role in this connection, as can be seen from

$$\Delta G^{\circ} = R \cdot T \cdot \ln \frac{C_2}{C_1} \tag{31}$$

where ΔG° is the difference in standard free energy, $R = 8.31\ \mathrm{J\,mol^{-1}\,K^{-1}}$, T = temperature in kelvin, and C_2, C_1 are higher and lower thermodynamic concentrations, respectively. Changes in concentration are a physical prerequisite for the production of a great many compounds, and an absolutely cogent one if substances are produced whose free energy is higher than that of the corresponding "raw materials."

On the nutrient-depleted soils of Amazonia (Fig. 25), for example, forest stands with their mosaic-like structure owing to the patchiness of rejuvenation processes (see Section 2.1.1) developed specific adaptations to facilitate these concentration processes. A dense root mat is formed over the soil in intimate contact with litter, with root tips growing upward into the fallen litter. Mycorrhizal associations, as the most common plant root – soil microorganism symbioses, benefit their host plants by effectively increasing the absorptive surface area of the root system, thus providing for increased uptake of nutrients. The dense fabric of predominantly fine roots also plays an important part in exchange and adsorption of nutrients from throughfall water. In addition, the structure of the foliage favors the use of nutrients during a long active life, the retransport of certain nutrients before leaf shedding, and a high polyphenol content and coriaceous nature, which both reduce herbivory. Another factor of great importance is the multilayered structure of the forest and the activities of epiphytes and microorganisms on much of the exposed surfaces, which together form highly efficient filtering systems scavenging nutrients from rainwater. Finally, biological nitrogen fixation in the root – humus – soil interface appears to play an important role in the nutrient budget [205]. Taking into account that even in the simplest cells the normal metabolic pathways imply several thousand complex chemical reactions that must be coordinated by means of an extremely sophisticated functional network, means that hierarchical order in both functional and spatiotemporal respects constitutes a further and most powerful negentropic factor. It characterizes every living system from the submicroscopic level to gigantic rain forest biomes such as the Amazonian Hylaea.

The effectiveness of these negentropic processes is further enhanced by most efficient entropy fluxes related to the transpiration and nocturnal respiration of plants. The molal entropy of H_2O increases from $63\ \mathrm{J\,mol^{-1}\,K^{-1}}$ (liquid) to $189\ \mathrm{J\,mol^{-1}\,K^{-1}}$ (gas) in the course of evaporation, and CO_2 has a molal entropy of $214\ \mathrm{J\,mol^{-1}\,K^{-1}}$. Consequently, the reverse process, the photosynthetic fixation of CO_2, is of comparable importance for the negentropy balance in the light of Equations (26) and (28).

As a consequence of these mechanisms, the results of the above comparative diversity analyses may be given a unified interpretation:

1) Species diversity is not a monotonous function of the nutrient status of soils. If soils form on basic or intermediate parent materials, pedogenic nutrient supply and species diversity may both increase during periods of $10^3 - 10^4$ (10^5) years, provided the water and energy factors are not limiting. In Figure 30, the period of ascending evolution is termed phase I. Shorter fluctuations of variable but generally decreasing amplitude are likely to be superimposed on this long-term trend. In phase II, which can last for several hundred thousand years, soils degrade in regard to nutrient supply, but species diversity keeps increasing for negentropic reasons (see the tropical rain forest stands in comparison to the ectoprical associations described in Section 2.3.3). Clearly such an evolution toward and including the following phase requires a sufficient degree of climatic and geomorphic stability (as has been the case in central Amazonia and considerable parts of Malesia), or else the continuity of pedogenesis will be interrupted by truncation processes that rejuvenate the soils (as happened in the major part of the Congo Basin). Phase III marks the eventual and comparatively acute decrease in diversity of phytocenoses once the nutrient status of soils has fallen below a critical level.
2) Spatial heterogeneity as a characteristic feature of the sites during phase I results in variability in the number of species and plant individuals. With this variability the associations can simultaneously retain genetic and behavioral types that can maintain their existence in low populations together with others capitalizing on opportunities for dramatic increase. The more homogeneous the environment in space and time (i.e., during phase II,

and probably also phase III), the more likely is the system to have low fluctuations (i.e., high stability). Tropical rain forests represent climatically buffered and (largely) self-contained systems with relatively low (natural) variability on highly impoverished soils of the ferralsol, acrisol, and podzol classes. Temporary external disturbances are consequently likely to affect a proportionally greater number of species than in phase I populations, where the interspecific differences in ecological potency are usually distinctly higher. Hence, resilience of mature biocenoses is low during phase II. In contrast, biocenoses may be highly resilient in phase III of evolution, although unstable.

The greatly reduced resilience of phase II stands is particularly well illustrated by the influence of clearing activities on tropical forests. The soil, with its low retention capacity, is irrevocably impoverished after a brief period of fertilization due to sudden release of nutrients in the biomass. The brief period of fertility is used by shifting cultivators to produce crops, but even this system, developed by small native populations "in close contact with the environment" [206], can induce severe losses if forced to fit a market-oriented economy or to feed larger populations [207], [208].

2.3.8. Appraisal

The analysis of real communities and the comparative assessment of ecological models [2], [37] show that real communities are not those homogeneous and temporally invariant systems described by simple Lotka – Volterra equations and exemplified by most laboratory microcosms. Population dynamics of real-world ecosystems are spatially distributed in general, associated with a marked temporal variation, providing a multitude of ways in which the probability of coexistence is enhanced and biodiversity increased. Coexistence under stochastic, nonequilibrium conditions as described by patch-dynamics models at different scales can be just as strong and stable as that occurring under a deterministic, niche-differentiation model [209].

In a single patch, species extinction can occur as a result of competitive exclusion, overexploitation, and other destabilizing interspecific interactions or be due to environmental instability (e.g., unpredictable disturbances or changes in conditions).

De Angelis and Waterhouse [210] and Remmert [211] have emphasized that the macroscale integration of unstable patches that are out of phase with each other can lead to persistent species-rich communities.

An important parallelism seems to exist between the properties of a community and the properties of its component populations, which will be subject to a (relatively) high degree of K selection in stable environments, while r selection (selection in the direction of high numbers of offspring) predominates in variable environments. The K-selected populations with their high competitive capacity, high inherent survivorship, and low reproductive rates are normally resistant to disturbances but, once perturbed, have little possibility of recovery (i.e., low resilience). The r-selected populations, by contrast, have less resistance but distinctly higher resilience. This inverse relationship between resistance and resilience is of particular importance in the ecotoxicological context (Section 3.2).

The above stability considerations mean that food chains should be shorter in "fluctuating" environments, since only the most resilient food webs would be expected to persist and short food chains are more resilient. An analysis of Briand's findings [184], however, shows that further critical tests of these logical ideas are required because the average maximal food chain lengths for 40 communities from both unstable and "constant" environments did not differ significantly. In conclusion, most communities are probably organized by a temporally and spatially varying mixture of " forces" – namely, competition, predation, and disturbances, with competition and predation being presumably less important in more disturbed environments [2], [212], [213]. Consequently, no single stability or sensitivity measure exists for a community. Stability varies with the aspect of the community or ecosystem under study and the nature of the disturbance. Without pertinent semantic specifications relating to defined temporal and spatial scales (duration and dimensionality of observations), indicator variables and the nature

Figure 30. Generalized model of long-term ecosystem evolution in reaction to nutrient supply of soil

of perturbation statements about system stability would be meaningless in a general ecological and a more specific ecotoxicological context.

2.4. Exposure and Effect Criteria of Chemicals

Methodologies for estimating fluxes, transformations, and resultant environmental concentrations of chemicals depend on the knowledge of how rapidly the chemicals are discharged to a specific compartment in the environment and how rapidly they are transformed or removed by physical, chemical, and biological processes. Apart from the specific structure of the receiving compartment, particularly its physical and chemical characteristics, these processes are largely controlled by the inherent molecular properties of the chemicals released. These may be appropriately classified as sets of equilibrium and kinetic constants that define the exposure potential, and a complementary set of data that characterizes the effect potential, i.e., the chemical, biotic, and particularly, ecotoxicological effects of a substance.

In the following sections the essential exposure and effect criteria are described. Other chemical and physical properties such as flash points, flammability limits, and autoignition temperature are omitted because they are not of direct concern to the environmentalist. A comprehensive review of these and other dangerous properties of chemicals is given in [214]. With regard to the following quantitative specifications, however, note that chemicals are never 100 % pure and that the very nature and quantity of the impurities can have a significant impact on many environmental qualities. In particular, the following parameters are very sensitive to the presence of impurities: water solubility, odor characteristics and threshold values, biological oxygen demand, and toxicity [47].

2.4.1. Equilibrium Constants for Chemical Distribution

Density, Molar Mass, and Structure. The density of a substance, particularly in comparison to that of water or air, is of special environmental importance since it largely controls dispersion processes. Hydrocarbons are usually lighter than water. Figure 31 illustrates the relationships of molar mass and density.

Melting and Boiling Points. Normally, melting involves an increase in volume by about 10 %; exceptions are water, bismuth, and gallium. According to the sign of this change in volume, melting temperature rises or falls by 0.01 – 0.1 K/bar, which means that, under environmental conditions, pressure has little effect on melting point.

The melting and boiling points of the members of homologous series of hydrocarbons increase with increasing molar mass. When comparing organic compounds containing different halogens, however, the mass effect can be (partly) counterbalanced by polarization effects (e.g., in the case of CH_3F and CH_3Br). Substitution of another atom or group for hydrogen in an alkane results in an elevation of the boiling point. Thus, alkyl halides, alcohols, aldehydes, ketones, and acids boil at higher temperatures than ("elementary") hydrocarbons with the same carbon skeleton. The introduction of groups promoting association brings about a marked rise in boil-

Figure 31. Relationships of molar mass and density (after [47], modified)
Dotted lines *I – VII* refer to right scale, lines *VIII – XIV* to left-hand scale

ing point, which is especially pronounced in alcohols and acids since hydrogen bonds can be formed [47].

Vapor Pressure, Vapor Density, and Volatility. The *vapor pressure* of a liquid or solid is the pressure exerted by the gas in equilibrium with the liquid or solid at a given temperature. The evaporative loss of a substance, volatilization, is a very important source of material for airborne transport and subsequent transformation and deposition processes. Vapor pressure data permit, in combination with solubility data, calculations of rates of evaporation of dissolved compounds from water by using Henry's law constant H, which is normally defined as

$$H = PS^{-1} \tag{32}$$

where P is the equilibrium vapor pressure of the pure chemical and S its saturation concentration or solubility at a fixed temperature.

Vapor density, compared to the density of air (=1), indicates whether a gas will be transported along the ground, possibly subjecting ecosystems to high exposure, or whether it will disperse rapidly. Vapor density is related to equilibrium vapor pressure through the fundamental state equation for a gas:

$$PV = nRT \tag{33}$$

If the mass of the substance and its molar mass are substituted for the number of moles n, this yields for the vapor density Vd [47]:

$$Vd = PM\,(RT)^{-1} \tag{34}$$

where P is the equilibrium vapor pressure (bar), $R = 8.31\ \mathrm{J\,mol^{-1}\,K^{-1}}$, M = molar mass (g/mol), and T = absolute temperature (K).

Volatilization of chemicals from water is an important transport process for a number of substances that have low water solubility and low polarity. Despite their very low vapor pressure, many compounds can volatilize rapidly because of their very high activity coefficients in solution, and by using the mathematical approach of Mackay and Paterson [215], [216] the rate constant for volatilization from water is given by

$$K_{\mathrm{vw}} = \frac{A}{V}\left(\frac{1}{K_{\mathrm{L}}} + \frac{RT}{HK_{\mathrm{G}}}\right)^{-1} \tag{35}$$

where A is the evaporating surface ($\mathrm{cm^2}$), V the liquid volume ($\mathrm{cm^3}$), H Henry's law constant (bar L/mol), K_{L} the liquid film mass-transfer coefficient (cm/h), K_{G} the gas film mass-transfer coefficient (cm/h), R the gas constant ($8.31\ \mathrm{J\,mol^{-1}\,K^{-1}}$), and T the temperature (K).

Volatilization processes from soil surfaces are complicated by variable contributions due to volatilization of the chemical from the water at the surface, evaporation of water itself, and the related capillary rise, which transports more water and dissolved chemical to the surface [217].

Water Solubility. Water solubility is an important parameter for the environmental assessment of all solid or liquid chemicals. In general, molecules with highly polar bonds will be relatively strongly attracted to one another; consequently, water and alcohol are potent solvents for ionic compounds such as salts, as well as polar nonionic molecules such as sugar. In contrast, nonpolar molecules such as tetrachloromethane, benzene, or gasoline are more weakly attracted to one another. They mix easily and are good solvents for nonpolar molecules, such as fats, grease, and paraffins, which are not soluble in water. Some solids are so firmly bonded that they are not significantly soluble in any common solvents except those with which they react chemically, whereby the nature of the molecule being dissolved is altered. Quartz is of this type: its solubility in pure water is of the order of 5 mg/L, but if the water contains a 0.01 M concentration of orthodiphenols, quartz is transformed into soluble esters and the solubility is increased to 40 mg/L [218].

The composition of natural waters varies considerably in space and time (see, e.g., [48]). Variables such as pH; water hardness; and concentration of cations, anions, and organic substances such as gelatin or fulvic and humic acids, all affect the solubility of chemicals in water.

Solubility of Mixtures. Mixtures of compounds behave differently from the individual compounds when brought in contact with water because each component partitions between the aqueous phase and the mixture. Compounds with a high water solubility tend to move into the aqueous phase, while the less soluble components have a greater tendency to remain in the mixture phase. Thus, the fractional composition of the water-soluble fraction differs from the original composition of the mixture, and the concentrations of the individual components of the water-soluble fraction are generally lower than their maximum solubilities [219].

***n*-Octanol – Water Partition Coefficient.** The n-octanol – water partition coefficient (K_{OW}) is defined as the ratio of the equilibrium concentration C of a dissolved substance in the two-phase system n-octanol and water (two solvents that are largely immiscible):

$$K_{\mathrm{OW}} = \frac{C_{\mathrm{octanol}}}{C_{\mathrm{water}}} \tag{36}$$

Usually the decadic logarithm of K_{OW} is given ($\log K_{\mathrm{OW}}$). Because K_{OW} is a dependent variable with regard to water solubility simultaneous

use of both in structure – activity relationships or multivariate classification procedures will give spurious correlations. Experimental determination of both the aqueous solubility and the *n*-octanol – water partition coefficient led to the following regression [220]:

$$\log K_{\mathrm{OW}} = 5.00 - 0.670 \log S \quad (37)$$

where S is the solubility in water (μmol/L). When solubility is expressed in mg/L, Equation (37) becomes

$$\log K_{\mathrm{OW}} = 4.5 - 0.75 \log S \quad (38)$$

The regression covers many classes of both liquid and solid compounds with highly different polarities, from hydrocarbons and organic halides to aromatic acids, pesticides, and polychlorinated biphenyls (PCBs). The corresponding correlation coefficient is 0.97, which normally allows an estimation within one order of magnitude of the partition coefficient of a given chemical from its solubility in water. However, the scatter increases considerably for solubilities greater than 100 mg/L, as the example of L-tyrosine shows, where the experimental value of $\log K_{\mathrm{OW}}$ is -2.26 while calculations using Equation (37) yield values of +2.7 or +2.5.

Furthermore, whether the above equations would also apply to chemicals with high dissociation constants, such as salts and strong acids or bases, is questionable since their activities in solution cannot be approximated by their concentration. Basically, the same restriction holds for aliphatic acids or bases whose partition coefficients can vary drastically with changes in pH [47], [221]. Nevertheless, the *n*-octanol – water partition coefficient has proved useful as a simple means of predicting biological uptake, lipophilic storage, and biomagnification factors (see Sections 2.4.2, 3.3.5 and Fig. 57), whereas extrapolations of the multifactorial soil adsorption processes are much more difficult.

2.4.2. Kinetic Constants for Environmental Processes

Every chemical reaction takes place at a definite rate depending on the specific conditions under which it occurs. These boundary conditions are the concentrations or pressure of the reacting substances, temperature, presence or absence of a catalytic agent, and radiation. Chemical kinetics deals with the rates and mechanisms of these reactions whose understanding is rendered difficult by the fact that both time and intermediate products are involved, compared to the subject of chemical equilibrium, which is concerned only with the initial and final states of reactants. Because of the complexity of these subjects, the following presentation is limited to determination of the essential rate constants for environmental processes from structure alone by using structure – activity relationships (see also → Toxicology, Chap. 2.).

2.4.2.1. Hydrolysis

Hydrolysis of compounds usually results in the introduction of a hydroxyl function and is most commonly associated with the elimination of a leaving group X:

$$\mathrm{RX} + \mathrm{H_2O} \rightarrow \mathrm{ROH} + \mathrm{HX} \quad (39.1)$$

In water, the reaction is catalyzed mainly by H^+ and OH^- ions; whereas in moist soil, loosely complexed metal ions such as copper or calcium may also constitute important catalysts for the hydrolysis of several types of chemical structures. In addition, sorption (→ Soil) of the chemical may increase its reactivity toward hydronium or hydroxyl ions [222], [223].

Mabey and Mill [224] reviewed kinetic data for hydrolysis of a variety of organic compounds in aquatic systems in relation to the chemical characteristics of most freshwater systems. Quantitative structure – activity relationships, used as predictive test methods to develop the essential kinetic data, generally take the form of linear free-energy relationships such as the Hammett and Taft

$$\log K_x / K_{\mathrm{o}} = \varrho\sigma \quad (39.2)$$

or Brønsted

$$\log K_x / K_{\mathrm{o}} = m\mathrm{p}K_{\mathrm{a}} + C \quad (39.3)$$

approaches, where ϱ is a constant for a given reaction under a given set of conditions, and σ is the Hammett constant, characteristic of a certain substituent; K_{o} and K_x are the rate constants for

the unsubstituted and substituted structures, respectively, while the dissociation constant pK_a refers specifically to the acidity of the leaving group.

Highly variable hydrolysis reactions have been observed in soil and sediment. This appears to be the result of unusual pH relationships at the surface of soil constituents, possible occurrence of metal-ion-catalyzed processes, and general acid- and base-catalyzed reactions, possibly involving phenolic, amine, or sulfide groups in soils [223]. In some cases (e.g., in the presence of clay minerals), hydrolysis rates of organic chemicals are accelerated considerably compared to bulk solution, while adsorption to humic components frequently impedes hydrolysis. A detailed understanding of the mechanisms involved is limited, however, and structure – activity relationships appear to be available for only a few compounds.

2.4.2.2. Photolysis

Direct Photolysis. Natural direct photolysis results from absorption of photons from the solar spectrum above 290 nm by the chemical. The specific absorption rate ($K_{a,\lambda}$) is a measure of the overlap between the solar spectrum and the electronic absorption spectrum of the compound (i.e., an inherent property of a photoreactive chemical) [225]:

$$K_{a,\lambda} = 2.303 E_0(\lambda)\,\varepsilon_\lambda \tag{40}$$

where $E_0(\lambda)$ is the scalar irradiance and ε_λ the molar absorptivity at wavelength λ.

Since pollutant concentrations are low under most environmental conditions, photolysis can be described by a first-order expression; i.e., the rate constant of direct photolysis k_d is directly proportional to pollutant concentration. From Equation (40), then

$$k_d = 2.303 \Phi_d \int E_0(\lambda)\,\varepsilon\, d\lambda \tag{41}$$

where integration is over the range of $Eo(\lambda)$, which is absorbed by the compound, and Φd denotes the quantum yield, which may attain a maximum value of 1. However, rapid direct photolysis can occur even with compounds that react with very low quantum efficiencies [225].

Since more than one primary reaction may be involved in a photochemical reaction, the primary quantum yield may be defined with respect to a specific reaction. Moreover, the sum of the quantum yields of all primary reactions, including deactivation, must be unity. The overall quantum yield, which is the quantity most often determined, on the other hand, does not distinguish between the effects of primary and secondary reactions and it may exceed unity.

Modeling photochemical reactions in natural waters is still in its infancy. No proven general model applicable to every kind of natural water is presently available for estimating the rates of consumption or production of chemical species through light-induced reaction pathways. A lot of fundamental and essential information for constructing a precise and realistic model is still not available. For example, the chemical composition of natural waters and their temporal and spatial variabilities are still inadequately known. Thus, the reactants that may participate directly and indirectly in photochemical reactions in a competitive, synergistic, or catalytic way cannot yet be fully identified. The rate at which a particular photochemical reaction may proceed in this poorly defined medium, and to which extend it will proceed cannot be quantified extensively by empirical data. Besides, as stated previously, even in a well-defined medium, the detailed reaction pathways of photochemical reactions can still rarely be identified definitively.

Indirect photolysis may occur if a natural material can absorb solar photons and transfer part of the energy to a chemical. Thus, compounds that do not absorb light directly can still undergo mediated photolysis, and chemicals that photolyze directly may photolyze much more rapidly in natural waters containing organic substances in dissolved or particulate form. Despite these difficulties, general rate expressions for sensitized photolysis can be defined. The rate of light absorption is

$$I^s_{a,\lambda} = 2.3 \varepsilon_{\lambda,s} E_o(\lambda)\,[S] \tag{42}$$

where $\varepsilon_{\lambda,s}$ is the molar absorptivity of the sensitizer and [S] is its concentration [225]. Thus, from Equation (42), the rate constants for indirect photolysis should increase with increasing [S] if $E_o(\lambda)$ is held constant. When the concentration of pollutant P is very dilute, the quantum

yield is directly proportional to this concentration. By denoting C_λ as the proportionality constant, the total rate expression becomes

$$(Rate)_\lambda = 2.3E_o(\lambda)\,\varepsilon_{\lambda,s}C_\lambda\,[S]\,[P] \quad (43)$$

Provided the sensitizer concentration is constant, which is usually the case in nature, the rate expression follows first-order kinetics (→ Air, Chap. 1.).

2.4.2.3. Oxidation and Reduction

Direct and indirect phototransformation as described in the preceding section are possible removal pathways only for those chemicals that, either by their very nature or due to fixation onto light-absorbing carrier substances, can absorb radiation in the range of the solar spectrum. However, the main transformations that lead to the removal of chemicals from the atmosphere and water involve reactions with photochemically generated *oxidants* such as the hydroxy radical (OH·), ozone (O_3), hydroperoxy radical ($HO\cdot_2$), organic peroxy radicals ($RO\cdot_2$), singlet oxygen ($O_2\,\Delta_g$), and nitrate radical ($NO\cdot_3$). Table 9 summarizes the reactivity of different classes of organic compounds toward some of the above oxidants.

Table 9. Rates of oxidation in air and water (after [222])

Type of oxidant	Class or structure	Half-life of reactant
HO· radical (in air)	*n*-, iso-, cycloalkanes	1 – 9 d
	alkenes	0.05 – 1 d
	halomethanes	0.2 – 100 a
	alcohols, ethers	1 – 3 d
	ketones	0.2 – 6 d
	aromatics	0.1 – 3 d
$RO\cdot_2$ radical (in water)	alkanes, alkenes	220 – 2000 a
	alkyl derivatives	220 – 2000 a
	phenols, arylamines	1 d
	hydroperoxides	150 min
	polyaromatics	10 d
$O_2\,\Delta_g$ (in water)	aliphatic compounds	100 a
	substituted or cyclic alkenes	8 – 40 d
	alkyl sulfides	1 d
	dienes	19 h
	enamines	15 min
	furans	1 h

The *reduction* of organic compounds requires an environment of low redox potential, i.e., eutrophic or deeper levels of aqueous systems and a soil depth at which oxygen is limited [226]. Reduction of organics can follow various mechanisms such as hydrogenation, halogenation, or coupled oxidation – reduction, many of which require catalysts. Like with many other chemical reductions, rates of reductive alteration of organics are temperature and pH sensitive [2]. Since the most common mechanism for reduction of organic molecules in the environment is via microbial attack, separating biologically induced from straight chemical reduction in situ is difficult. From the viewpoint of prospective hazard assessment, however, identifying those compounds that are potentially susceptible to reduction and the transformation products that might be deposited in the environment as a result is more important.

2.4.2.4. Sorption and Ion Exchange

Further processes of fundamental importance for the distribution of environmental chemicals in water and soil are sorption and ion exchange. Adsorption is the adhesion of ions or molecules to surfaces or to solid – liquid, liquid – gas, and liquid – liquid interfaces, causing an increase in the concentration of chemicals on the surface or interface over the concentration in solution. Adsorption occurs as a result of a variety of processes with a multitude of mechanisms when the concentration of chemicals lowers the free interfacial energy. The higher the free surface energy at an interface, the greater is the number of substances capable of lowering it.

Physical Adsorption. Molecules of a given material may be adsorbed from the gas or liquid phase to a solid by van der Waals forces. This process resembles a condensation that reaches equilibrium in a time limited chiefly by molecular diffusion rates. The weakness of van der Waals forces is reflected in the low adsorption enthalpy of physiosorptive (or unspecific) bonding; it amounts to hardly more than 40 kJ/mol [227]. Reversibility is a characteristic of physical adsorption that results from rapid equilibration; i.e., at a given temperature and pressure the same amount of material is adsorbed regardless of the direction from which equilibrium pressure and temperature have been approached. From the environmental point of view, however, the

fact that physical adsorption of gases by highly porous media such as silica gel, charcoal, and soil often exhibits "hysteresis," a form of irreversibility due to condensation of liquid in pores is very important. Analogous phenomena occur with chemicals bonded at solid – liquid interfaces.

Chemical Adsorption. Molecules of a given substance may also be adsorbed from the liquid or gas phase by a solid through the activation of valence forces. Consequently, they may be considered as reacting with atoms or molecules on the surface of the solid in a way analogous to any other chemical reaction, and the products of this reaction are usually conveniently considered to be species quite different from the original reacting molecules of the atoms (chemisorption or specific bonding in terms of soil chemistry). Temperatures at which chemisorption occurs are related not to the boiling point of the adsorbate (material being adsorbed), as is the case with physical adsorption, but to the stability of the surface compound and its rate of formation. Therefore, rates of chemisorption vary enormously with material and temperature, as do those of ordinary chemical reactions, and may be very much slower than rates corresponding to diffusion of gases or solutes to the surface. Furthermore, the rates are likely to vary strongly with the amount of material adsorbed. Because of these rate characteristics, the amount of adsorbate at a given pressure or concentration and temperature – when observed over practical time periods – may depend strongly on the way these boundary conditions have been reached. Therefore, irreversibility is extremely common in chemisorption, which is characterized by enthalpy values >100 kJ/mol [227].

Ion Exchange. The presence and extent of ionization also have a great influence on the chemical behavior of a substance, particularly on solubility, sorption, toxicity, and other biological characteristics. Ion exchange as an important sorption mechanism for substances prone to ionization is viewed as an exchange with some other ion that initially occupies an adsorption site on the solid (→ Ion Exchangers) [226]. For example,

$$\mathrm{H^+}\,\overbrace{\underbrace{\mathrm{Al^{3+}}}_{\mathrm{K^+\,Na^+}}}^{\mathrm{Ca^{2+}\,Mg^{2+}}} + 10\,\mathrm{NH_4^+} \rightleftharpoons \mathrm{NH_4^+}\,\overbrace{\underbrace{\quad}_{2\,\mathrm{NH_4^+}}}^{4\,\mathrm{NH_4^+}}\,3\,\mathrm{NH_4^+} \qquad (44)$$
$$+\,\mathrm{H^+} + \mathrm{K^+} + \mathrm{Na^+} + \mathrm{Ca^{2+}} + \mathrm{Mg^{2+}} + \mathrm{Al^{3+}}$$

The ion-exchange property of a soil results mostly from the clay and silt fractions, organic matter, and hydrous oxides of iron. Soil particles have an amphoteric character but normally carry a net negative charge. Positive charges, as indicated by the amphoteric nature of the clay fraction, may originate from hydrous oxides of iron (ferrihydrites), aluminum, and manganese, and from exposed octahedral groups that react as bases by attracting protons from the surrounding soil solution. The negative charge increases and the positive charge decreases with rising pH as a result of increasing ionization of the acid groups and decreasing protonation of the basic groups. For decreasing pH, the corresponding change occurs in the opposite direction. The carboxyl groups of humus ionize under acid conditions, the phenolic hydroxyl groups mainly above pH 6. Because of the highly irregular shape of many clay minerals (and clay – humus complexes, in particular) and the nonuniform distribution of charges in the particles, the surface charge density is quite variable.

To describe ion-exchange processes, several formulas have been proposed in the course of exchange studies. The first group is essentially empirical and intended mainly to provide mathematical formulations best fitting the experimental data. Among this group, the Freundlich [49], Langmuir, and BET (i.e., Brunauer – Emmett – Teller) are particularly important [228]. The second group of formulas is related to the law of mass action.

Empirical Adsorption Formulas. In the *Freundlich equation*, the concentration of a substance in solution is related to that adsorbed as follows [49]:

$$\frac{x}{m} = kc^{\frac{1}{n}} \qquad (45)$$

where x is the amount of substance adsorbed; m the mass of the adsorbent; c the concentration of substance remaining in solution; and k, n are specific constants.

The Freundlich formula is of a parabolic type and therefore cannot give a maximum adsorp-

tion value as does the *Langmuir theory.* According to the latter, adsorption is considered proportional to the pressure of gas (or concentration of a solute) and to the amount of surface not yet covered with adsorbed molecules. The rate of desorption (or evaporation) of adsorbed molecules is considered proportional to the number of such molecules. At equilibrium, these two rates must be equal; thus,

$$\frac{n}{n_{\mathrm{m}}}=\frac{bp}{1+bp} \tag{46}$$

This equation, in which n is the number of molecules adsorbed, n_{m} the number of molecules required for a completely unimolecular surface film, p the concentration of a chemical in solution, and b a constant at a given temperature, is the *Langmuir adsorption equation* (*Langmuir isotherm*).

A third theory of adsorption widely used for representing the adsorption of gases or vapors on solids was advanced by Brunauer, Emmet, and Teller [228]. In contrast to Langmuir's theory, the *BET theory* makes allowance for adsorption of multimolecular layers as is commonly observed when nonporous solids adsorb vapors at pressures approaching saturated vapor pressure. The BET equation is therefore

$$\frac{n}{n_{\mathrm{m}}}=\frac{b\frac{p}{p_0}}{\left(1-\frac{p}{p_0}\right)\left[1+(b-1)\frac{p}{p_0}\right]} \tag{47}$$

where p_0 denotes the saturation vapor pressure, while the other quantities have the same meaning as in Equation (46). The equation is designed for physical adsorption and predicts a very sharp increase in the amount of material adsorbed as the saturated vapor pressure is approached, and this is found to be the case [50].

2.4.2.5. Biotransformation

Biotransformation is a more accurate and general term than biodegradation, because many chemicals are transformed to products of comparable molecular complexity instead of being degraded. Chemically speaking, biotransformation in water and soil systems includes hydrolysis, oxidative cleavage, and reduction, even in aerobic systems. Kinetics of biotransformation are normally based on the Monod model [51], which couples the rate of loss of the chemical to the growth of organisms involved. In the natural environment, however, growth is usually controlled by nutrients present in comparatively constant amounts, and the kinetic expression for biotransformation processes simplifies to a second- or pseudo-first-order reaction:

$$d\,[C]\,/dt=k_{\mathrm{bt}}\,[\mathrm{C}]\,[\mathrm{B}]=k'_{\mathrm{bt}}\,[\mathrm{C}] \tag{48}$$

where d [C]/dt is the rate of transformation of C; [B] is the number of organisms per unit volume; k_{bt} the second-order rate constant for biotransformation; and k'_{bt} the pseudo-first-order rate constant. The half-life of the chemical under transformation ($t_{1/2}$ at a given cell concentration) can then be calculated as

$$t_{1/2}=\frac{\ln 2}{k_{\mathrm{bt}}\,[\mathrm{B}]} \tag{49}$$

In deriving this equation, the microbial community in water, sludge, or soil is assumed to already be acclimated to the chemical, so no lag time is involved in production of the necessary level of biotransforming organisms or appropriate mutants or enzymes.

Because of the remarkable versatility of microorganisms in their catabolic activity, many substances are subject to microbial mineralization or cometabolism in water and soil. If, however, microorganisms have no enzymes active in a necessary catabolic sequence or if the substrate is protected from microbial attack because of special properties of the environment, the compound tends to persist. In some instances, persistence may be attributed to absence of the requisite enzymes or to the lack of permeability of microorganisms to the substrate [229]. Other mechanisms of recalcitrance may be inherent in the molecule itself; in some cases, biotransformable compounds are degraded quickly in one environment but are partially or totally refractory in another.

2.4.2.6. Chemical Structure and Biodegradation

Biodegradation is the most important transformation mechanism for organic compounds in nature. It can occur under conditions in which

oxygen is present (aerobic) or absent (anaerobic). In aerobic processes, organic carbon is oxidized to CO_2, while in anaerobic processes it may ultimately be reduced to CH_4. In either case, the more important environmental variables affecting the rate and extent of biodegradation are temperature, pH, salinity, oxygen concentration, concentration of the chemical involved, ionic strength, composition of microbial associations and concentration of viable microorganisms, quantity and quality of nutrients (other than xenobiotic substances), trace metals, and vitamins.

In general, microbial degradation is impeded by ether bonds and by triple-substituted or condensed phenyl groups–particularly, if the latter have methoxyl, sulfone, nitro, or chlorine substituents in the *meta* position. Among the nitrophenols and chloroanilines, the *ortho*-isomers are relatively recalcitrant. Multiple substitution increases the recalcitrance of aromatic molecules considerably because their aerobic degradation is effected by relatively specific mono- and dioxygenases [229], [230]. Halogen substituents delay the electrophilic attack of these oxygenases considerably by reducing enzyme affinity. Therefore, multiple chlorine-substitued aromatics form relatively persistent compounds, the more so because the delayed cometabolic attack yields "dead-end" metabolites, which cannot be used for cell-building purposes or as an energy source.

Anaerobic Processes. As a consequence, reliable conclusions about biodegradation are not generally possible on the basis of chemical structure alone [47]; therefore, many laboratory methods have been developed for studying the aerobic biodegradative potentials of chemicals [231–234]. In comparison, tests for assessing anaerobic biodegradation have received less attention [84]. Nevertheless, anaerobic degradation is an important process for substances that are not aerobically biodegradable or whose physicochemical properties are such that their occurrence in an aerobic environment is restricted (e.g., chemicals that are strongly adsorbed or insoluble). For these substances, anaerobic biodegradation can be the major process responsible for breakdown in the environment.

Anaerobic biodegradation is complex and usually considered to occur in at least three consecutive main stages, the first of which involves hydrolysis of complex organic molecules such as carbohydrates, proteins, and lipids by the action of extracellular enzymes. In the subsequent stage (acidogenic step), the hydrolysis products are fermented to yield mainly short-chain fatty acids, alcohols, hydrogen, and carbon dioxide. Alcohols and acids are then converted in the acetogenic step. The last degradation step is effected by methanogenic bacteria (methanogens), which utilize acetate and hydrogen to form methane.

Anaerobic processes tend to be self-inhibitory because the hydrolysis of complex substrates such as fats, proteins, and carbohydrates yields volatile organic acids. By lowering the pH of the system, these may inhibit the growth of methanogens unless the system has sufficient buffer capacity [84]. Inhibition of gas production as a result of the toxicity of chemicals is also possible. Finally, some indications have been found that certain compounds (e.g., nitrilotriacetic acid) are degraded anaerobically only when aerobic organisms acclimatized to the compound are incorporated in the system [235].

When the organic compound liable to degradation or enzymatically induced metabolic transformations is utilized as a carbon source, the growth rate of the responsible microorganism depends on the concentration of the former. The rate of substrate utilization then becomes [52]

$$\begin{aligned} -dC/\mathrm{d}t &= \mu X/Y = (\mu_\mathrm{m}/Y)\cdot CX/(K_\mathrm{s}+C) \\ &= k_\mathrm{b}\cdot CX/(K_\mathrm{s}+C) \end{aligned} \tag{50}$$

where μ is the specific growth rate; X the biomass per unit volume; μ_m the maximum specific growth rate; K_s the concentration of the substrate to support half-maximum specific growth rate ($0.5\,\mu_\mathrm{m}$); $k_\mathrm{b} = \mu_\mathrm{m}/Y$, the biodegradation constant; and Y is the biomass produced from a unit amount of substrate consumed. The constants μ_m and K_s depend on temperature, pH, salinity, oxygen concentration, concentration of chemical, composition of microbial associations, and concentration of viable microorganisms, quantity and quality of nutrients (other than xenobiotic substances), trace metals, and vitamins.

2.4.2.7. Bioconcentration, Bioaccumulation, and Ecological Magnification

Bioconcentration is the concentration of a chemical in an organism due to direct uptake from the environment (e.g., ambient air or water), which does not include contaminated food. *Bioaccumulation* includes the latter pathway of concentration, while *biomagnification* considers only concentration processes via food uptake. *Ecological magnification* defines the increase in concentration of a substance in an ecosystem or a food web when passing from a lower trophic level to a higher one [53].

Bioconcentration or bioaccumulation is the result of both kinetic (diffusional transport and biodegradation) and equilibrium (partitioning) processes. It thus involves the following set of fundamental events [47]:

1) Partitioning of the xenobiotic between the environment and some surface of the organism
2) Diffusional transport of the molecules across cell membranes
3) Transport processes mediated by body fluids, such as exchange between blood vessels and serum lipoproteins
4) Concentration of the xenobiotic in various tissues depending on its affinity for specific biomolecules such as nerve lipids
5) Metabolism, cometabolism, or biodegradation of the xenobiotic

The relative importance of the above processes is likely to differ considerably as a result of both the physicochemical properties of the xenobiotic and the morphological and physiological structure of the target organisms. Therefore, an essential ecotoxicological requirement is that the determination of bioconcentration factors (*BCF*s) be complemented by an assessment of biomagnification values. Under real-world conditions, these would provide deeper insight into the complex bioaccumulation processes of xenobiotics as a result of transport and partitioning into higher levels of the food web, which may ultimately result in toxic concentrations [235].

On the basis of bioconcentration studies in different test organisms, correlations with both water solubility and *n*-octanol – water partition coefficients have been established. In some cases, the results proved excellent; in others, the correlations yielded only satisfactory structure – activity relationships (i.e., estimates of *BCF*s to within an order of magnitude for chemicals of $\log K_{ow}$ ranging from 1 to nearly 7).

3. Ecotoxicology

The production, use, and disposal of chemicals lead to their dispersion in the environment. The way in which substances are released depends on their physical and chemical properties (see Section 2.4.1), the production process (→ Production-Integrated Environmental Protection ; → Plant and Process Safety), including extraction of natural resources (→ Raw Materials and Energy) and manufacturing; and the use pattern and means of disposal (→ Waste).

Figure 32. Component-specific influence of two xenobiotics on an ecosystem (after [159], modified)
Substance (1) affects a functionally central component, thus causing breakdown of the whole ecosystem. Substance (2) affects a peripheral component; even its deletion leaves the ecosystem practically unchanged.

Compartments of ecosystems have a limited capacity to assimilate chemicals by breakdown or dilution; if this capacity is exceeded, damage may ensue. Thus, the hazard posed by a single substance or a mixture of chemicals is a function of its inherent toxicity to organisms and the concentration attained. At the community and ecosystem levels, the sensitivity has to be considered specifically (Section 2.3), i.e., the functional position of the organisms affected with regard to the entire system. Figure 32 illustrates schematically the different influence of xenobiotics, affecting two elements of an ecosystem. In case (2), only a peripheral element (in the func-

tional sense of the term) is damaged or deleted, which leaves the system relatively intact. In case (1), however, a component of central importance is eliminated, which leads to breakdown of the entire system.

Thus, the assessment of whether a substance presents a hazard to organisms in the environment is based on a comparison of its predicted environmental concentration (PEC) with the predicted no-effect concentration (PNEC) for organisms in the ecosystem affected. Whenever the PEC : PNEC is <1.0, a substance may be concluded not to present an environmental hazard under the boundary conditions considered. In the opposite case, hazard assessment should be complemented by risk assessment approaches, which define the probability that a hazard will occur. Figure 33 illustrates the temporal and spatial scales that must be considered when analyzing the impact of environmental chemicals on biota or ecosystems.

PEC values can be measured in the field. The identification of unequivocal spatial structures related to emission, transport, and sedimentation normally involves the construction of isopleth maps by means of metric interpolation. A pertinent statistical method that permits testing the validity of interpolation procedures is variogram analysis, normally applied in conjunction with kriging methods (i.e. methods in geostatistics for valid derivation of isopleths) [236], [237] (Section 3.1.4). Alternatively, the predicted environmental concentration can be estimated, if the manner and quantity in which a chemical enters the environment, and its subsequent distribution and transformation, are known (see Section 2.4.2; [2], [238]). This normally involves the application of models that are available at different levels of complexity, ranging from empirical models for practical purposes to rather abstract ones aiming at generalized insights via simulation.

Effects assessment establishes a maximum concentration of a substance that does not cause adverse effects. The PNEC values may be derived from whatever ecotoxicological data are available, by using simple mono- and oligospecific test systems, or micro- and mesocosms, and ideally from toxicity measurements at the ecosystem level. The lower the level of assessment approach, the more appropriate are assessment factors to compensate for restrictions in the data.

3.1. Exposure Assessment

Exposure assessment involves the identification of point or diffuse emission rates and the subsequent distribution tendencies, based on predictive models. In the first assessment step, the initial concentration ($PEC_{initial}$) in each compartment of concern must be estimated. If necessary, a revision in light of relevant new information may lead to a revised $PEC_{initial}$ and a PEC_{local} or a $PEC_{regional}$. The PEC_{local} is the estimated concentration of a substance when released to a particular environmental compartment, with further fate processes, (e.g., volatilization, sorption, biodegradation) taken into account. The $PEC_{regional}$ denotes the predicted concentrations of a substance in all relevant compartments, when the further distribution and fate of the chemical are taken into account.

3.1.1. Release Estimation

For realistic exposure assessments, basically the entire life cycle of a chemical should be analyzed and PEC values calculated for each relevant process. To standardize the release estimation for screening purposes [239], the EEC and OECD have defined three different categories of use pattern: main, industrial, and use. The main category classifies substances in four groups (see Table 10).

Table 10. Release fractions in the screening phase of hazard assessment of chemicals related to the main category (after [239])

Main category	Release fraction of production volume	Examples
Closed system	0.01	chemical intermediates
Enclosed in a matrix	0.1	plastic additives
Nondispersive	0.2	photochemicals
Wide dispersive use	1.0	solvents, plant protection products, detergents

In addition to the main categories, there are 15 different “industrial” categories and 55 different “use” categories [240]. This classification scheme allows a stepwise approach in release

Figure 33. Temporal and spatial scales of the impact of chemicals on biota (after [53], modified)
MFO = monooxygenases

estimation. In the screening phase a rough estimate based on the main category may be sufficient, whereas in the confirmatory phase more refined release data (e.g., based on other categories) are needed. In the investigation phase, finally, detailed information on specific releases of the substance is required (→ Chemical Products: Safety Regulations, Chap. 3.).

3.1.2. Elimination

A reduction in the concentration of chemicals in gaseous or aqueous discharges prior to their release to the environment is termed elimination. Elimination may be due to physical, chemical, or biochemical processes. The most significant elimination mechanisms are biochemical processes, especially aerobic biodegradation by bacteria or an alternation of aerobic and anaerobic phases (see Section 2.4.2) [2], [35]. Physical processes transfer a substance from one phase to another. In the case of volatile substances, the aeration process normally enhances their removal by stripping them from the solid or liquid phases to the atmosphere [47]. Substances from exhaust gas streams may be eliminated by scrubbing, e.g., by adsorption on a suitable material or passage through a suitable aqueous solution.

3.1.3. Dispersion

Pollution transport and dispersion are directly related to wind speed or flow velocity of rivers, etc. The higher the velocity, the greater is the volume of air passing a point source per unit time, and the lower is the resultant concentration per unit volume. Higher wind speed also means greater turbulence, which involves fluctuations of the local wind vector on various scales, and these eddies act to diffuse a plume. In addition to this "stretching" phenomenon [241], wind speed is important for the transport distance. In strong winds, pollutants may be transported long distances, but the resultant dilution over 10 – 50 km is usually such that most individual plumes have lost their identity and contribute to a more general (background) contamination of the lower atmosphere. Consequently, weaker regional wind systems may exhibit much greater potential for pollution since both horizontal transport and eddy diffusion are reduced.

This simple fact becomes all the more important because, under these conditions, local wind systems tend to develop that are difficult to predict with any accuracy [54]. In so far as they are closed smaller-scale circulations (e.g., land and sea breezes, mountain and valley winds, city winds), they often produce recirculation of pollutants coupled with a progressive increase in pollutant loading with time. The city thermal wind system operating mainly in the urban canopy layer is particularly dangerous; it is produced by microscale processes in the streets [242–244]. Here, flow converges on the city (or its variable thermal subcenters) from all directions, rises, diverges, and then moves outward to subside on the urban – rural fringe, where it rejoins the inflow.

The worst conditions for dispersion, however, occur in the case of temperature inversion and consequent formation of a stable boundary layer. With the warmer air layer acting as a lid on the mass of cooler air below, pollutants cannot escape from the cooler zone and thus increase in concentration in the confined space. This situation can be brought about by cooling (usually radiative) from below, by warming (usually adiabatic) from above, or by advection of warmer or cooler air.

Since the 1970s, modeling of dispersion processes in air has become more and more sophisticated owing to the progressive consideration of pertinent boundary layer effects and concentration or removal processes ([245–248], e.g.). This involves not only a considerable increase in computer time but also, and often more prohibitive, much more detailed input data. In the light of these circumstances, a question of practical importance is whether simpler models are not likely to yield comparable results on the condition that their data base can be made proportionally more comprehensive.

Box models, including dry and wet deposition and chemical transformations, are likely to provide calculated concentrations that are in reasonable or good agreement with measured values on a local scale as well as with transport data over a distance of 1000 km. An exemplary prototype whose fundamentals have often been used was developed by [249], describing SO_2 and NO_x concentrations in the industrial areas

of North Rhine – Westphalia along the Rhine and Ruhr rivers.

Statistical models define immission concentrations by means of multiple regression relating immissions to emissions, meteorological parameters, topography, or other dispersion-controlling factors. Models of this type vary considerably with respect to both regression analytical approach and selection of data.

Observations of looping, coning, or (to a lesser degree) fanning plumes on an instantaneous basis reveal that the concentration is very peaked, with a marked maximum in the plume center. Averaged over growing time intervals, an increasingly smooth and wide plume envelope appears, which contains all of the short-period plume fluctuations. The wider spread results in a flatter concentration curve, with a correspondingly lower peak centered on the time mean axis of the plume (i.e., the mean wind direction). Analogous bell-shaped or Gaussian concentration profiles also characterize the vertical plane through the plume, although there may be a difference between the width of the horizontal and vertical profiles indicating that turbulence is greater in one or another direction.

Eulerian or Grid Model. The Eulerian or grid model is a mathematical representation of the pertinent transport processes and chemical reactions occurring in a grid of cells yielding the spatial and temporal variations of the ground cell concentrations of primary and secondary pollutants. It is characterized by fixed coordinate systems with respect to the ground and consists of a set of nonlinear coupled partial differential equations expressing the conservation of mass of each pollutant considered. Inputs to the model are numerical representations of the meteorological and emission conditions as a function of time of day, initial concentrations, and boundary conditions of inflow.

Lagrangian Model. In the trajectory or Lagrangian model, the time behavior of the concentration c of a pollutant is described by a differential equation of the type

$$\frac{\partial c}{\partial t} = \frac{\partial}{\partial z}\left(\underline{K}\cdot\frac{\partial c}{\partial z}\right) + S \qquad (51)$$

where c depends only on height above ground z and the time of travel t of an air parcel, while S refers to the net source – sink term representing the combined effects of emissions and chemical processes during transport, deposition, and flow across the upper boundary. $\underline{K}$ represents a vertical eddy diffusion coefficient whose values characteristically depend on time of day, height, and location. In comparison with the above Eulerian models, trajectory models have commendable mathematical advantages resulting from their moving coordinate systems with respect to a fictitious vertical air column moving horizontally with the advecting wind [250]. Considered as the present state of the art in operational long-range transport modeling, the Lagrangian approach has been used in numerous studies in the United States and Canada relating to transboundary air pollution.

3.1.4. Local and Regional Concentration Estimates

After emission, the environmental fate of a substance is governed by both transport and transformation processes that may be assessed by measurements or modeling approaches of which there are two basic types. The *local* or *monocompartment approach* is focused on the distribution of a substance within a particular environmental compartment, which leads to a $\mathrm{PEC}_{\mathrm{local}}$. The *regional* or *multicompartment approach* is directed toward the overall distribution, where transport occurs in all relevant environmental compartments (i.e., air, water, or some other medium) leading to $\mathrm{PEC}_{\mathrm{regional}}$ values.

The first approach is appropriate if the degradation rate is (distinctly) greater than the intercompartmental transfer rate; otherwise a multicompartment or multimedia approach is indicated (Section 3.3) [251]. Irrespective of the type of model to be used, the environmental parameters such as compartment volumes or compartment ratios must be defined; they are sensitive points for the final result. For substances that enter the environment from diffuse emission sources, a realistic PEC estimate cannot be calculated by means of the habitual point-source models. In such cases, the exposure assessment must be based on scale considerations and spatial modeling [252].

3.1.4.1. PEC Estimates in the Air Compartment

For the primary exposure assessment, models of advection and related dispersion processes may be used that compute concentrations of a substance at different receptor compartments. These require different minimum data sets consisting of discharge emission rates, effective height of source, and meteorological conditions, (stability classes of atmosphere, wind speed etc.). For regulatory purposes, the TA Luft model [253] is widely used (see also Section 3.1.3; → Air).

For subsequent revisions of the exposure assessment, information on the long-term fate of the chemical in the atmosphere is required. This involves the appropriate consideration of direct and indirect photodegradation and other chemical reactions [245], [254]. The reactivity of the hydroxy radical formed predominantly via photolysis of ozone by reaction of electronically excited oxygen atoms with water vapor is of fundamental importance in this connection.

A balance must be struck between simple models that do not represent the real-world situation and models that are too difficult to use. Thus, level 1 (equilibrium, conservative, steady state) and level 3 models (nonequilibrium, nonconservative, steady state) in the sense of the MACKAY et al. classification [251] are considered useful simple approaches. Level 2 models (equilibrium, nonconservative, and steady state) usually are of minor interest, whereas level 4 models (nonequilibrium, nonconservative, nonsteady state) should be used only for estimating disappearance of chemicals from the environment [238].

An important drawback of these "unit world" models is that they compute only one concentration value for each compartment, whereas measurements normally indicate that actual concentrations in the environment may range over several orders of magnitude. Thus, they are suited only to provide an indication of concentrations in places far from the source (i.e., background levels). Improvements are possible by performing a sensitivity analysis, by using statistical approaches, or by adapting the unit world to the region of interest [255], [256]. An alternative method is the application of dispersion models, provided that appropriate input data, representative dispersion parameters, and sufficient meteorological information are available (see Sections 3.1.3, 3.3).

3.1.4.2. PEC Estimates in Soil and Subsoil

Xenobiotics in soil and subsoil generally result from agricultural or industrial activities. The main problems in recent years were related to the application of manure and fertilizers, pesticides, sewage sludge, and to contaminated sites (see → Soil, Chap. 5., [2], [48]). Table 11 illustrates, on a comparative basis, heavy-metal concentrations in Schleswig-Holstein soils. In the light of the very high spatial variability of the soil cover, representative sampling is particularly important for concentration measurements. Regionalized variables should be applied to adequately characterize the chemical soil properties under consideration; consequently, variogram analysis in combination with kriging procedures is the appropriate method (see → Soil, Chap. 6.; [159], [236]).

3.1.4.3. Variogram Analysis

Mathematical Concept. A regionalized variable can be considered the realization of a random function Y. Usually, this function is assumed to be stationary; this implies the following:

1) The expectation (m) of Y at any point of x is constant and independent of x.

$$E\left[Y\left(x\right)\right] = \left(m\right) \tag{52}$$

2) The covariance function of any pair of points $\boldsymbol{x}$ and $\boldsymbol{x}+\boldsymbol{h}$ depends exclusively on the vector $\boldsymbol{h}$ and is independent of $\boldsymbol{x}$

$$E\left[Y\left(\boldsymbol{x}\right)Y\left(\boldsymbol{x}+\boldsymbol{h}\right)\right] - m^2 = K\left(\boldsymbol{h}\right) \tag{53}$$

In many cases, only the increments of the functions are supposed to be stationary. The intrinsic hypothesis for a vector $\boldsymbol{h}$ concerning expected value and variance is

$$E\left[Y\left(\boldsymbol{x}+\boldsymbol{h}\right) - Y\left(\boldsymbol{x}\right)\right] = 0 \tag{54}$$

$$Var\left[Y\left(\boldsymbol{x}+\boldsymbol{h}\right) - Y\left(\boldsymbol{x}\right)\right] = 2\gamma\left(\boldsymbol{h}\right) \tag{55}$$

The so-called semivariogram (designated "variogram" further on), i.e., the function of the vector $\boldsymbol{h}$ is defined as

$$\gamma(\boldsymbol{h}) = 1/2Var\left[Y(\boldsymbol{x}+\boldsymbol{h})\,Y(\boldsymbol{x})\right] \tag{56}$$

From Equations (55) and (56),

$$\gamma(\boldsymbol{h}) = 1/2E\left[Y(\boldsymbol{x}_i+\boldsymbol{h}) - Y(\boldsymbol{x}_\mathrm{i})\right]^2 \tag{57}$$

In case of discontinuous data the expected value ($\boldsymbol{h}$) can be estimated by the formula

$$(h) = \frac{1}{2n}\sum_{i=1}^{n}\left[Y(\mathrm{x}_i+\mathrm{h}) - Y(\mathrm{x}_i)\right]^2 \tag{58}$$

where n is the number of pairs of points.

The points are situated in either one-, two- or three-dimensional space. In two-dimensional space as dealt with here, the coordinates h_1 and h_2 determine the vector $\boldsymbol{h}$. Hence, the variance of measured values depends on the distance and the direction of the difference vector $\boldsymbol{h}$.

In practice, the variogram is usually computed for four main axes (Fig. 34) to account for possible directional effects. Distinctions of the range in different directions (anisotropy) then enable a more detailed interpretation. A mean variogram that is independent of such directional effects is usually computed on the basis of the four directional variograms. A variogram is geometrically characterized by two boundary criteria called "sill" and "range" (Fig. 35). The latter denotes the maximum extent of influence, while the former is the analogous limiting value of influence as measured on the ordinate.

Figure 34. Principal axes of a variogram

Interpretation of the Variogram. *Zone of Influence*. The foregoing indicates that a variogram does not necessarily have a maximum or a level of stabilization. Because of this, two basic types of variograms are distinguished (Fig. 36). In Figure 36 A the maximum range is reached when the correlation between $Y(\boldsymbol{x})$ and $Y(\boldsymbol{x}+\boldsymbol{h})$ becomes nil

$$\gamma(\mathrm{h}) = 1/2Var\left[Y(\mathrm{x}+\mathrm{h}) - Y(\mathrm{x})\right] \tag{59.1}$$

$$= 1/2\left\{Var\left[Y(\mathrm{x}+\mathrm{h})\right] + Var\left[Y(\mathrm{x})\right]\right\} \tag{59.2}$$

$$= \frac{2\sigma^2}{2} = \sigma^2 \tag{59.3}$$

This means that a mathematically meaningful interpolation is possible if and only if the maximum distance between neighboring points of measurement is shorter than the distance indicated by the range value of the variogram. In Figure 36 B the zone of influence extends beyond the area examined.

Mathematical Models of the Curve. To best fit the curve of the variogram under construction to the sequence of points obtained primarily from computation of the variance function, various mathematical models are used, the most important of which are described briefly (Fig. 37). Power functions (Fig. 37 A):

$$\gamma(\boldsymbol{h}) = C\,|\boldsymbol{h}|^{\gamma} \quad \text{with}\, 0<\gamma<2 \tag{60}$$

$\gamma(\boldsymbol{h}) = C$ — $\boldsymbol{h}$ — is the special case of a linear model. Spherical model (Fig. 37 B):

$$\gamma(\mathrm{h}) = C\left[3/2\frac{\mathrm{h}}{a} - 1/2\frac{|\mathrm{h}|^3}{a^3}\right] \quad \text{for } |\mathrm{h}| \le a \tag{61}$$

$$\gamma(\mathrm{h}) = c \text{ for } |\mathrm{h}| > a$$

Exponential model (Fig. 37 C):

$$\gamma(\mathrm{h}) = C\left[1 - e^{\frac{-|\mathrm{h}|}{a}}\right];\ a \simeq 1/3 \text{ of range} \tag{62}$$

Gaussian model (Fig. 37 D):

$$\gamma(\mathrm{h}) = C\left[1 - e^{\frac{-|\mathrm{h}|^2}{a^2}}\right];\ a \simeq 0.58 \times \text{range} \tag{63}$$

Often, for a more exact fit the models must be combined. The variance of the sample is approximately the same as the value of the sill as far as bounded variograms are concerned. The model of the curve is important primarily for determination of the "nugget effect," a phenomenon that must be dealt with when the curve's behavior near the origin is considered.

Figure 35. Sill and range of an experimental variogram

Figure 36. Bounded (A) and unbounded (B) variogram

Behavior of the Curve near the Origin.

1) A parabolic shape shows a high degree of continuity of the regionalized variable. It is differentiable.
2) A linear shape shows continuity "in average" according to MATHERON [236].
3) The curve does not intersect the abscissa at the origin. The nugget effect reveals great irregularity and can be caused fundamentally either by an extremely discontinuous distribution in the immediate neighborhood of the sample taken or by observational errors. Supplementary information is consequently needed.
4) A straight line parallel to the abscissa indicates that no correlation exists between any points $Y(\boldsymbol{x}+\boldsymbol{h})$ and $Y(\boldsymbol{x})$ whatever their distance might be. The sample does not show any spatial structure.

Anisotropies. Distributions characterized by different variabilities in different directions are reflected in the resulting variogram and called anisotropy.

1) Geometrical or affine anisotropy exists whenever elliptical zones of influence can be deduced in a two-dimensional space
2) In a three-dimensional space, variations might also appear in the vertical direction; this is the case of stratified anisotropy

3.1.4.4. Modeling Chemical Distribution in Soil and Subsoil

Assessing chemical concentrations in soil by means of models normally involves two basically complementary approaches. One type of model simulates chemical movement in the unsaturated zone, (i.e., from the soil surface down to the water table); the other describes chemical transport in the saturated zone or aquifer. BONAZOUNTAS [258], FRÄNZLE [2], and MATTHESS [48] provide state-of-the-art reviews of these models.

Figures 38 and 39, representing one of the most comprehensive hierarchical models developed so far [252], illustrate that the two most important factors influencing chemical behavior in the unsaturated soil zone are sorption and biotransformation. The essential boundary conditions and processes involved (Section 2.4) are indicated in the model that is free from limiting meso- and macro-scale assumptions such as homogeneity (i.e., homogeneous compartments and uniform distribution of chemicals) and stationarity (i.e., large-scale equilibria in extensive compartments). Extended versions of this model serve specific purposes, e.g., modeling of carbon and nitrogen fluxes through ecosystems (Fig. 40).

Small-Scale Assessment of Chemical Distribution. Fate and behavior of chemicals can be described approximately by means of table functions, see Table 12 [259]. In combination with geographic information systems, they permit the production of smaller-scale single-species sensitivity or distribution maps. Six parameters, defined in score form on a 0 (practically none) to 5 (very much, very high) scale, are employed to describe chemical reactions in soil:

1) Solubility in mg/L (20°C) 0: <0.1, 1: 0.1 – 1, 2: 1 – 10, 3: 10 – 100, 4: 100 – 1000, 5: >1000
2) Adsorption, as defined by the Freundlich k values for organic matter (k_{oc}) and clay (k_c) at a soil – solution ratio of 1 : 2 0: <0.5, 1: 0.5 – 50, 2: 50 – 150, 3: 150 – 500, 4: 500 – 5000, 5: >5000 pH influence + or − (i.e., adsorption increases with increasing or decreasing pH)
3) Degradability, defined in terms of time required to produce an approximately 90 % transformation at a soil temperature ranging

Figure 38. Soil moisture module of the integral WASMOD/STOMOD model (Wasserhaushaltsmodell/Stoffflußmodell, after [252], modified)

from 11 to 16 °C: 1: >3 years, 2: 1 – 3 years, 3: 18 weeks to 1 year, 4: <18 – 6 weeks, 5: <6 weeks

4) Volatility, defined by the vapor pressure of the pure substance in (hPa) at 20 – 25 °C: 1: $<10^{-3}$, 2: 10^{-3} – 100, 3: 100 – 500, 4: >500 or Henry constants 1: $<4\times10^{-6}$, 2: 4×10^{-4}, 3: 4×10^{-4} – 0.04, 4: >0.04

In considering the influence of organic matter content on the adsorption process, the average scores of Table 12 must be defined more precisely according to Table 13. Further refinements relate to texture, pH value, temperature, etc. (Tables 14, 15, 16).

3.1.4.5. PEC Estimates in Aquatic Compartments

Establishing valid monitoring networks or sampling grids poses distinctly lesser problems in surface waters than in soils, but the inherent difficulties should not be underestimated. For instance, determination of the surficial nitrate concentration pattern in a dimictic – holomictic lake of about 1-km^2 size requires 40 – 50 stations [167]. For other chemical species, network densities must be higher still in the light of variogram-analytical evaluations.

In the light of these technical difficulties, modeling approaches play a considerable role

Table 12. Behavior of organic chemicals in soil (after [259], for explanation of figures see)

[238]. Differentiation between large-scale dilution models operating at the regional level, (e.g., a whole river), and site-specific models requiring a more specific characterization of the projected site is indicated. Simple dilution models assume a homogeneous distribution of chemicals in a water body; i.e., for a given set of stream or river and sewage treatment (→ Wastewater, Chap. 1.) or discharge conditions, an average concentration is calculated. Site-specific models may yield concentration profiles of a chemical in the water body. Also concentrations of chemicals released into the river at many points can be estimated by dilution modeling. The simulation then comprises a relatively large region, typically a major catchment or an entire country. When a sufficient amount of data on dilution factors is available, chemical exposure can be expressed in the form of PEC frequencies in the rivers considered.

The data required to run a surface water model relate to the character of the chemical, the hydrological structure of the catchment, and

the discharge pattern [238]. The chemical data include molar mass, melting and boiling points, water solubility, ionization constant, and kinetic parameters relating to sorption, volatilization, photolysis, hydrolysis, oxidation, and biotransformation processes (see Section 2.4). Environmental data vary according to the complexity of the model, beginning with a stream dilution figure for a whole region and ending with more sophisticated approaches based on data on the number and discharge flows of sewage treatment plants and the flow regimes of rivers of a major catchment. Additional site-specific input data may include hydraulic geometry of channels, sediment load, terms of the catchment water balance, physical and chemical characteristics of the water body and its suspended and bottom sediments, etc. In addition, basic dilution models require data on the fraction of the chemicals released to the drain and its removal in different types of sewage treatment. Site-specific models require additional data on chemical loading for each simulated compartment. For spill models, volume and density of the spill are needed [260], [261].

For specific purposes, aquatic equilibrium modeling may become necessary to predict environmental concentrations more reliably. To this end, fast reactions of inorganic species dissolved in aqueous media can be classified under the following categories:

1) Reactions with solvent molecules, in particular dissociation
2) Substitution reactions with solvent or dissolved species
3) Redox reactions with dissolved gases or other ionic species

These reactions can lead to the formation of new complex ions with different ligands in the coordination sphere, ions with different oxidation state of the metal centers, or still other ions. The reactions are essential, since the medium in which the particular inorganic substance is dissolved largely determines the speciation of the particular metal ion. In addition, upon mixing of solutions of these metals with the environment, chemical modification of the species will occur initially by thermodynamically favored rapid reactions and subsequently by slower reactions [262–264]. The following slower reactions are important in aqueous media [258]:

1) Ligand substitution reactions of kinetically relatively inert ions
2) Electron-transfer reactions involving inner-sphere mechanisms for relatively inert ions and some outer-sphere reactions
3) Reactions with dissolved gaseous species or bacterially induced reduction
4) Precipitation of solids by formation of insoluble species through substitution reactions
5) Formation of metal hydroxides and sulfides by oxidation reactions

These slower reactions impact the speciation and concentration in the aqueous phase and determine both type and extent of further interactions in a way comparable to fast reactions. Therefore, the time frame for some of the above reactions may indicate that characterizing the speciation in the original aqueous phase will also define the chemical behavior of the compound in the environment, whereas in other cases, understanding speciation implies exact knowledge of environmental interactions. To this end, a larger number of speciation models have been developed to address a series of specific situations. They are based on chemical thermodynamic reactions and principles, and also account for additional processes such as redox reactions [265], adsorption [266], complexation [267–269], ligand exchange [270], and others [271].

3.2. Effects Assessment

The assessment of possible effects of chemicals on the environment involves the determination of no-effect concentrations (PNECs) for aquatic species, edaphic species, and for species that may be affected by ecological magnification, i.e., by accumulation of substances through the food web. In addition, assessment procedures are indicated for substances that may have a negative impact on natural physicochemical processes in the atmosphere (for definitions and terminology of risk, see Appendix, Chap. 4).

Hitherto the predictive assessment of dose – effect relationships between chemicals and biotic elements in the environment has usually started with laboratory tests. Their results need extrapolation to the complex real-world situation, which proves rather difficult, as a rule,

since the experiments are performed with defined amounts of chemicals in contact with a single species or restricted group of organisms. In contrast, the integral approach to assessing the effects of potential pollutants in the natural environment has to deal with the manifold interactions and complicating factors or boundary conditions, which are carefully avoided or controlled in the laboratory situation (see also → Toxicology, Chap. 3., → Toxicology, Chap. 4., → Toxicology, Chap. 5.).

The following are most prominent of these complicating factors in the natural environment [272]:

1) Uneven distribution of the pollutant in an ecosystem compartment because of gradients or currents, dilution, volatilization, sorption processes, etc. Bioaccumulation in successive elements of the food web may cause considerable variations in the individual load of different species.
2) Differences in specific sensitivity may lead to shifts in the abundance and diversity proportions of the biocenoses affected. Interspecific relationships, synergistic relations, and food web effects can be analyzed only in multispecies systems.
3) In a natural ecosystem, the effect of a pollutant on the biocenosis will be greatly influenced by weather, diurnal and seasonal variations, simultaneously occurring variable loads such as thermal and chemical loads, along with intermittent discharges.

To a certain extent, the influence of these complications can be accounted for by simulation techniques in the laboratory, but practical limitations necessarily exist. On the other hand, retrospective field experiments alone cannot be relied on since the doses are not known exactly, intentional pollution for experimental purposes is frequently prohibited, and biological observations are time-consuming and expensive. As a consequence, comparative tests should be carried out with selected model chemicals under both laboratory and natural conditions to determine the relative representativity of the test procedure. This validation of the tests should also pay appropriate attention to the important question of how far the test system or the experimental field plot is representative from a regional point of view [160].

In comparing this comprehensive, normative list of ecotoxicological models with the (still) predominant present-day practice, a fairly marked tendency exists to favor the bioindicator approach and aquarium or microcosm tests or technically comparable procedures [273], [274]. This has the appreciable advantage of relative simplicity and ensures a fairly high amount of reproducibility, but also poses the above problems as to rationally and reliably extrapolating to the complex real-world situation.

3.2.1. Test Systems for Aquatic Ecosystems

3.2.1.1. Level 0

Test procedures on the infraorganismic level (i.e., organells, cells, tissues) are omitted here and the hierarchical system suggested in the OECD Chemicals Testing Programme is followed [275]; consequently three successive levels of sophistication labeled 0, 1, and 2 are distinguished. The results of level 0 tests together with an increase in production of the chemical considered and its type of use pattern should indicate that subsequent tests on higher levels have to be carried out.

The following set of studies is considered relevant for the level 0 dossier:

1) Acute toxicity study with *Daphnia magna*
2) Acute toxicity study with fish
3) A static biodegradation test

According to the 7th Amendment to the Directive 67/548/EEC, Annex VII A, the minimal data basis (base set) for effects assessment purposes comprises acute tests for fish, *Daphnia*, and algae. In the OECD testing hierarchy, the latter forms part of level 1 enquiries.

Toxicity Test with *Daphnia magna*. The water flea *Daphnia magna* (Daphniidae, Cladocera) is a suitable test organism for static and semistatic tests and for flow-through systems. The results of these tests are relevant for initial hazard assessment because of the trophic importance of daphnids as primary consumers, their sensitivity to chemicals, and their relationship to various other ecologically important aquatic invertebrates. Also, automatic biomonitoring devices are feasible. The tests usually consist of two phases:

1) An acute phase that gives the 24-h EC_{50} value, the highest concentration that still causes no immobilization (EC_0), and the lowest concentration that causes 100 % immobilization (EC_{100})
2) A reproduction phase yielding the EC_{50} and LC_{50} values at 24, 48, and 96 h; 7 and 14 d; and the end of the test (further information is provided by time span until the emergence of the first brood, the number of live and dead young, their condition, etc.)

The slope of the time – response curve depends largely on the speed and degree of absorption, inherent detoxification, and excretion mechanisms. While a steep slope usually indicates rapid absorption and toxic effects appearing within a short period of exposure, a shallow slope may be due either to low absorption or to toxic effects delayed beyond the period of observation.

The 14-d effect level in relation to the 24-h LC_{50} is, to a certain extent, indicative of the potential for chronic toxicity of a compound. Since the test duration is limited to two weeks, however, it may provide misleading results if the chemicals considered are taken up slowly or have delayed toxic activity. Yet the *Daphnia* test is in any case useful for determining whether further ecotoxicity studies are necessary to indicate which parts of an ecosystem or which species are most sensitive. A low effect concentration may trigger further tests while, conversely, a relatively high *Daphnia* effect concentration may guide any further testing away from invertebrates [276], [277].

Acute Toxicity Studies with Fish. Fish are of particular importance in aquatic environments, and their survival in waters bears witness to the absence of toxic substances or adverse conditions for the species in question. Consequently, toxicity tests with fish have been carried out in laboratories for about a century, but not infrequently the results obtained have differed widely because of lack of standardization of test organisms and boundary conditions.

Therefore, considerable numbers of studies have been undertaken since the 1970s to define the parameters involved in performing toxicity tests: taxonomy, age, and size of fish; composition of environments, in particular pH value, buffering capacity, mineral and organic content, temperature, and oxygenation; duration of contact with toxic substances; etc. The result has been the perfection of numerous techniques that can be applied in fresh water or seawater; they yield satisfactory results, depending on their objectives, although they cannot always be applied readily to other cases in view of major differences in the experimental conditions and the sensitivity of species selected.

Species frequently used in such studies are *Brachydanio rerio*, *Carassius auratus*, *Leuciscus idus*, *Phoxinus phoxinus*, *Rasbora heteromorpha* (Cyprinidae); *Jordanella floridae*, *Oryzias latipes* (Cyprinodontidae); *Poecilia reticulata* (Poeciliidae); and *Oncorhynchus mykiss* (Salmonidae). They comprise species that occur in aquatic environments into which the chemicals under study are released and so-called aquarium fish, which (frequently) are not representative of natural environments but are more suitable for screening tests.

The acute toxicity test on fish [275] is specifically designed to estimate the LC_{50} with observations after 24, 48, 72, and 96 h. However, the longer durations are reported to yield possibly misleading results because test organisms are not fed during the experiment [278]. The resulting data are used to prepare concentration – mortality curves with LC_{50} values, which also permit estimation of the maximum concentration causing no mortality and the minimum concentration causing 100 % mortality. Where possible, LC_{50} values are also estimated for each of the recommended observation times, thus giving a more precise indication of the time – toxicity curve.

As for Daphniidae, comparison of the LC_{50} values with the potential environmental concentrations of a chemical will provide a first crude estimate of the potential hazard to fish. When the slope of the curve is steep and soon tends to be asymptotic to the time axis, longer exposure is not likely to result in a significant increase in mortality unless noxious effects that result from different mechanisms are delayed. Conversely, where the slope is shallow, cumulative toxicity and subsequent chronic effects may be indicated and an extension of the test period could result in a considerably lower LC_{50} estimate. For a more detailed review of the increasing range of types of acute toxicity tests on fish, see [47],

[275], [278], [279]. In view of the numerous tests suggested, however, one should note that environmentally acute lethal toxicity is not the major problem. Acute lethal poisoning is easily detectable and should be readily controllable as well. Thus, subchronic and chronic exposures are likely to be the sources of problems. Consequently, obtaining information on the approximate magnitude of acutely lethal concentrations over an exposure period of up to 96 h might appear sufficient: "The greater the range of water qualities in which the acute LC_{50} is measured and the greater the variety of fish species used, the more likely is it that sufficiently cautious estimates can be arrived at. In this field of toxicity testing it is more important to get some measure of the variability existing, and ever perhaps try to account for it, than it is to mask any real differences which exist by conveniently standardizing tests. (Standard tests with fish appear, in fact, not to be concerned with the assessment of toxicity as such but rather with reproducibly bioassaying the concentration of a given chemical in some particular quality of water)" [280].

Tests for Biodegradation. Assessment of the environmental hazard of a particular chemical involves a prediction of interactions that may lead to degradation of the chemical or its eventual accumulation in particular environmental compartments. In the framework of the OECD Chemicals Testing Programme [275], the following test procedures *defining ready biodegradibility* have been suggested:

1) Modified AFNOR test
2) Modified Sturm test
3) Closed bottle test
4) Modified OECD screening test

These tests provide limited opportunities for biodegradation and acclimatization. Hence, a chemical giving a positive result may be assumed to biodegrade in the environment rapidly and, therefore, may be classified as "readily biodegradable."

Modified AFNOR Test. The modified AFNOR test requires a test material that must at least be soluble at the concentration tested [40 mg dissolved organic carbon per liter (DOC/L)] have negligible vapor pressure, not be inhibitory to bacteria, and not significantly adsorb on glass surfaces. The test substance is degraded by chemicoorganotrophic microorganisms added in low concentrations with the products used as the sole source of carbon and energy. The organic carbon remaining in solution after 3, 7, 14, 28 (and 42) d is measured, and the corresponding level of biodegradation calculated. A detailed description of the test, which is sensitive to an order of magnitude of $\pm 10\,\%$, is given in AFNOR T-90-302 Test and the OECD Guideline 301 A [231].

Modified Sturm Test. The modified Sturm test has the same requirements as the preceding one, but uses the amount of CO_2 produced as indicator variable [281]. To this end, a chemically defined liquid medium, essentially free of other organic carbon sources, is spiked with the test substance and inoculated with a low concentration of sewage microorganisms. The CO_2 released is trapped as $BaCO_3$. By reference to suitable blank controls, the total amount of CO_2 produced by the test compound is determined and calculated as the percentage of total CO_2 (TCO_2) that the chemical tested could have theoretically produced in relation to its carbon content. In the absence of toxic effects on the inoculum, the reproducibility of the Sturm test is $\pm 5\,\%$. Unless the test is adapted to handle ^{14}C-labeled compounds, test chemical concentrations cannot be lower than 5 mg/L [231].

Closed Bottle Test. The purpose of the closed bottle test is measurement of the biodegradability of organic compounds in an aerobic, aqueous medium at a test concentration of 2 (i.e., standard concentration) to 10 mg/L of active material. The degradation or biotransformation is given as the biochemical oxygen demand (BOD) within 28 d as a percentage of either the theoretical oxygen demand (TOD) or the chemical oxygen demand (COD) [231]. Most data elaborated with this test pertain to water-soluble compounds, but volatile compounds and those of low water solubility may also be tested, at least in principle. In the closed bottle test, a predetermined amount of test substance is dissolved in a mineral nutrient solution to provide the above concentration of active substance per liter. The solution is inoculated with a small number of microorganisms from a mixed population (derived from unfertilized garden soil and activated sludge) and kept in closed bottles in the dark in a constant temperature bath at $20 \pm 1\,°C$. Degradation is followed by oxygen analyses over a

28-d period. A control with inoculum, but without test material, is run parallel for the determination of oxygen blanks. The reproducibility of the test is appropriate for screening purposes but not sufficient for a final decision regarding biodegradability. Although most experience has been gathered with water-soluble chemicals, the structure of the tests also permits, in principle at least, application to volatile and insoluble compounds.

Modified OECD Screening Test. The modified OECD screening test aims at measuring the ultimate biodegradability of water soluble, nonvolatile organic compounds in an aerobic, aqueous medium with a starting test concentration of 5 – 40 mg DOC per liter. Degradation is calculated as the percentage DOC removal within 28 d with respect to the test material. The compound to be tested is dissolved in an inorganic medium (i.e., a mineral nutrient solution, fortified with a trace element and essential vitamin solution), providing the above concentration. The solution is inoculated with a small number of microorganisms from a mixed population and aerated at 20 – 25 °C in the dark. Degradation is determined by DOC analysis over the 28-d period, which is checked by means of a standard. A control with inoculum, but without test material or standard, serves to determine DOC blanks [231]. Data obtained from these and similar tests are applicable only to aerobic biodegradation. Since a more comprehensive evaluation of the possible fate of a chemical must also take anaerobic situations into account, other test procedures may become necessary.

Other Tests for Ready Biodegradability. At least some 20 additional methods have been suggested to evaluate biodegradation in surface waters or sewage treatment plants [47]. On the basis of comparative degradation tests, Gerike [282] came to the conclusion that determination of DOC removal usually yields the most reliable and relevant results and could therefore constitute the major source of primary information on ready biodegradability.

Tests for Inherent Biodegradability. Substances that are not readily biodegradable in terms of the above or comparable tests may be examined with the aim of assessing their intrinsic potential for biodegradation (i.e., their liability to microbial breakdown under favorable conditions). At present, the modified Zahn – Wellens test and several methods for assessing the biodegradation potential of soil are available for determining inherent biodegradability [283].

The *Zahn – Wellens test* [284] has a number of advantages. As a batch die-away test, it employs activated sludge, mineral nutrients, and the test substance in solution as the only source of carbon. The mixture is agitated and aerated in a 1 – 4-L glass under diffuse illumination for up to 28 d. Degradation is monitored by determining the DOC (or COD) values in the (filtered) solution at regular intervals. The ratio of eliminated DOC (or COD) after each interval to the initial concentration is expressed as percentage biodegradation; plotted versus time it gives the biodegradation curve. This test provides a good indication of inherent biodegradability and permits acclimatization phenomena to be detected from the degradation – time relationships recorded. Its drawback lies in the high initial concentration of the test substance, which may exert toxic effects on the inoculum [284]. Like some others, the Zahn – Wellens test is suitable only for water-soluble, nonvolatile compounds.

The principle of the inherent biodegradability test in soil is described in OECD Test Guideline 304 A [234]. A small (50-g) sample of soil is treated with the ^{14}C-labeled test chemical in a biometer flask apparatus. The amount of $^{14}CO_2$ released from the test substance is absorbed in a 0.1 N KOH solution and determined by liquid scintillation counting. The test is one example of a class of indirect estimations of microbial degradation processes that generally rely on some unique characteristic of the compound in question, such as the release of $^{14}CO_2$ or of chloride from organics containing organically bound chlorine. Destruction of aromatic compounds in model systems can also be detected in the loss of ultraviolet light absorbance as the aromatic ring is cleaved [285].

Direct Measurement of Ecotoxic Substances. Among the direct measurement methods, gas chromatography provides a rapid, simple, and highly sensitive tool, especially in combination with mass spectrometry and in the form of multidimensional headspace capillary gas chromatography. The latter method increased the reliability of the qualitative and quantitative analysis of volatile compounds by the simultaneous chromatographic separation of samples in two

capillary columns of different polarity. It is not affected by disturbances due to salts and compounds with higher molar mass and avoids effects otherwise exerted by the extractant used. By virtue of its high degree of mechanization, headspace injection can be automated easily.

Bioassays. In bioassays for the degradation of toxic compounds, a plant, insect, microorganism, or other suitable indicator organism that is sensitive to the treated sample is exposed at regular intervals after initial modification of the soil. The substance or its inhibitory derivatives are assumed to remain as long as the susceptible species or strain fails to grow or develops atypically, and the length of incubation of the soil required before the indicator organism starts developing in the test sample as well as in untreated soil is considered a reflection of the time at which the toxic component has dissipated [286].

3.2.1.2. Level 1

Subject to positive results from the acute toxicity tests of level 0, an increase in production of the compound, and a risk estimate associated with the use pattern intended, the following test procedures are foreseen for the level 1 dossier:

1) Chronic toxicity study with *Daphnia magna*
2) Subacute toxicity study with fish
3) Algal test
4) Test for species accumulation
5) Additional biodegradation test

Chronic Toxicity Study with Daphnia Magna. The chronic toxicity study with *Daphnia magna* is thought expedient if the LC_{50} appeared lower than 100 mg/L, and it should also include determination of the "no-toxic-effect levels" for both reproduction and lethality. For higher LC_{50} values, such a test appears justified only on the condition that biodegradation has not been proved by the relevant test carried out on level 0.

Subacute Toxicity Study with Fish. The subacute toxicity study with fish is a medium-term test with an exposure time of at least 14 d. As such, it is generally dynamic and based on the substantiation of lethal or sublethal effects on growth, behavior, or reproduction, including the determination of "threshold levels." If the LC_{50} for fish has been assessed at values lower than 1000 mg/L, the same species is to be used for the subacute toxicity study. For higher LC_{50} values, such a test appears necessary only if the previous biodegradation study yielded inconclusive results [287].

Algal Test. An algal test [275] enables a determination of the effects of a substance on the growth of unicellular green algae under laboratory conditions over a period of several cell generations. Since algae, as primary producers, are at the very base of aquatic food webs, their increase or decrease may influence higher trophic levels in natural aquatic ecosystems. In this respect, the possible toxic influences of a chemical on algal growth are highly relevant for the assessment of potential effects in the natural environment. The value of the test is, however, necessarily limited by the inherent difficulty of extrapolating laboratory conditions to the natural situation with its involvement of many other biotic and abiotic factors.

To obtain reproducible results, the algae (frequently *Chlorella pyrenoidosa*, *Scenedesmus quadricauda*, or *Scenedesmus subspicatus*) are exposed to the test substance at defined concentrations for 96 h. The algal growth, measured by the increase in biomass or cell number, is determined at least 24, 48, 72, and 96 h after the start of the test, and the corresponding concentrations per milliliter are calculated. The EC_{50} value is calculated graphically or by computation.

For assessment purposes, both the intrinsic growth rate (i.e., slope of the curve during logarithmic growth) of the control and experimental algal population and the total yield have proved useful. Even if the 96-h EC_{50} value does not seem to reflect high toxicity, this may be due to the fact that the test chemical has degraded considerably in the course of the test.

Test for Species Bioaccumulation. The potential of a chemical to bioaccumulate in aquatic organisms is determined by means of a sequential static test for species bioaccumulation, for which fish are preferably the animals of choice. Bioaccumulation is expressed by the bioconcentration of the chemical in the test organism relative to that in water under steady-state conditions [234]. In the first step of the test procedure,

the time interval necessary to reach the steady-state concentration is determined by exposing one group of fish to one concentration of the test chemical without renewal of the test solution. In the second step, the dependence of bioaccumulation on various (i.e., at least three) concentrations of the test chemical is determined, and the result obtained is expressed in form of a sorption isotherm. In the third step of the procedure, the duration rate is measured. To this end, fish exposed to the maximum test compound concentrations in the preceding step are transferred to noncontaminated water from which the depurated compound is continually removed. The residual concentration in the fish is determined periodically until about 80 % depletion is reached or for a period of up to ten days, whichever comes first.

The test for species bioaccumulation was established with ^{14}C-labeled pesticides such as 2,4-D, atrazine, DDT, and others; consequently, such compounds can be appropriately used for standardization. The use of nonlabeled chemicals as standards requires highly sensitive (ppb-range) and compound-specific analytical methods. With respect to specificity, the test is suitable for nonionized organics that are not readily biodegradable, are relatively stable in the aquatic environment (i.e., half-life >4 d), are soluble in water at <2000 ppm (μg/g), and have an *n*-octanol – water partition coefficient (K_{ow}) >1000 and a volatility (i.e., water – air partition coefficient) >100.

With regard to direct bioaccumulation in individual species, it clearly correlates with the degree of lipophilicity, expressed in terms of the *n*-octanol – water partition coefficient (see Section 2.4.1). Exceptions normally relate to cases where K_{ow} overestimates the bioconcentration factor. The higher the K_{ow} of a chemical (i.e., the more lipophilic it is) the slower is it depurated (desorbed) from the organism. Since this process does not always follow first-order kinetics, however, apparent half-lifes should not be extrapolated beyond the ranges measured.

In addition, reactions of chemicals in living organisms may result in derivatives that are more lipophilic than the parent compound or in binding (parts of) the chemical to special cell constituents. The latter applies, in particular, to inorganic or organometallic chemicals. Clearly, in either case, the K_{ow} value of the parent compound as such is not an appropriate indicator of the bioaccumulation potential. For organic compounds ionizing under physiological conditions (i.e., in the pH range 3 – 9), K_{ow} is predictive only if the chemical has no specific reactivity to cell constituents.

If the studies carried out on level 0 did not yield a satisfactory amount of information about biodegradation, another *static biodegradation test* can be chosen. If its result is negative again, a dynamic test in a flow-through system on the basis of lower concentrations, together with another inoculum, should then be used.

3.2.1.3. Level 2

The results of studies carried out on test level 1 are preferably to indicate which tests are to be made on level 2; this level is characterized by

1) An additional test for bioaccumulation
2) A chronic toxicity study with fish
3) An acute and a subacute toxicity test with another organism

Additional Bioaccumulation Studies. In the framework of supplemental bioaccumulation studies, the water solubility and *n*-octanol – water partition coefficient of the chemical in question merit particular attention (Section 2.4.1). Depending on the results of the previous accumulation test on level 1 and the physical and chemical properties of the compound, a flow-through test may be appropriate. It provides an opportunity for more adequate regulation of test conditions, including actual exposure concentrations, and is not limited in duration, thus allowing more comprehensive assessment of the significance of exposure time in evaluating bioaccumulation. The test substances are dissolved, if necessary with surfactant, in water. The solution is introduced continuously into an aquarium with constantly flowing water where the test fish are kept. The concentrations of chemicals in both water and test fish are analyzed, and the BCF is calculated. Since the variability of bioconcentration factors in several fish species is fairly high, it may be useful to achieve a higher degree of normalization by relating BCFs to the lipid content of the fish.

A technical advantage of the easily applicable test [288] is the possibility of automatic control.

The dissolved oxygen concentration, pH, water temperature, etc. can be automatically and continuously measured and recorded.

Chronic Toxicity Study. A chronic toxicity study with fish is indicated if the "no-effect level" for reproduction is more than a factor 10 lower than the no-effect level for lethality of *Daphnia magna*. The same applies if the threshold level for fish as determined under level 1 is 10 times lower than the LC_{50} for fish. According to the relevant OECD Test Guideline [287], fish such as the aforementioned *Poecilia*, *Oryzias*, and *Jordanella* species should preferably be used as test organisms. On the basis of present limited experience, the tendency is to believe that the results of a toxicology study with a second species are not likely to change the estimated "no-toxic-effect" level to a great extent. Therefore, acute and subacute toxicity studies with another aquatic or terrestrial species, for instance the Japanese quail, should be performed only if the need is really indicated.

Representatives of the trophic levels described are listed below. Standard organisms are underlined. The assignment of an organism to a trophic level is based on the energy balance of the ecosystem considered and does not depend primarily on the species. Therefore, a population may represent more than one trophic level in dependence on the nutrition available for the species. In addition, earlier life stages often live on completely different nutrition compared to adults of the same species.

Primary Producers. Primary producers photo- or chemoautotrophically synthesize organic compounds using inorganic precursors. They include

1) Chlorophyll-containing species of vascular plants
2) Algae (e.g., green algae: *Selenastrum*, *Scenedesmus*, *Chlorella*; blue-green algae: *Microcystis*)
3) Purple sulfur bacteria, chlorobacteria
4) Chemoautotrophic bacteria (nitrifying bacteria, sulfur bacteria)

Primary Consumers. They live mainly on living or dead autotrophic organisms or on microorganisms. Representatives of this trophic level are especially plant-eating animals (i.e., species that are not carnivorous) of the following taxonomic groups:

1) Protozoa (e.g., *Uronema, Entosiphon, Tetrahymena*)
2) Annelids (e.g., *Tubifex, Enchytraeus*)
3) Crustacea (e.g., *Artemia*, *Daphnia sp.*, *Copepoda*, *Gammarus*, *Asellus*)
4) Mollusks (e.g., *Dreissensia, Mytilus*, *Ostrea*; several gastropods: *Patella, Viviparus*)
5) Insects (some insect larvae that are not carnivorous)
6) Nematodes (species that live in water)

Secondary Consumers. They live mainly on primary consumers. Among them are

1) Predatory insects and larvae of insects (e.g., *Chaoborus*)
2) Carnivore protozoa
3) Rotatoria
4) Coelenterates (e.g., *Hydra*)
5) Predatory copepods
6) Fish (Teleostei: e.g., *Cyprinus carpio, Brachydanio rerio, Poecilia reticulata, Oryzias latipes, Pimephales promelas, Lepomis macrochirus, Oncorhynchus mykiss* (former: *Salmo gairdneri*) *Leuciscus idus melanotus, Cyprinodon, Carassius*
7) Amphibians (e.g., *Rana*, *Xenopus*)

Decomposers. Organisms of this trophic level break down dead organic material to inorganic constituents. Representatives are

1) Bacteria (most species)
2) Fungi

Test organisms for benthic ecosystems

Biological group/test organism	Parameter tested
Benthic invertebrates	
Panagrellus redivivus	survival
Caenorhabditis elegans	survival
Tubifex tubifex	survival
Stylodrilus heringianus	survival, repellency, rate of transformation of the sediment, growth
Hyalella azteca	survival, growth, reproduction
Pontoporeia hyi (*Diporeia sp.*)	survival, repellency
Corbicula fluminea	survival, growth
Anodonata imbecilis	survival
Chironomus tentans	survival, growth, hatching
Chironomus riparius	survival, growth
Hexagenia limbata	survival, frequency of exuviation
Macrobenthic biocenoses	indices for biocenoses and populations
Macrophytes *Hydrilla verticilata*	length of shoots and roots, dehydrogenase activity, chlorophyll-a, peroxidases

3.2.1.4. PNEC Values and Assessment Factors

The function of hazard or risk characterization and assessment is the overall protection of the environment. With regard to aquatic ecosystems, two habitual assumptions are therefore made to extrapolate from the above single-species short-term toxicity data to ecosystem effects: (1) ecosystem sensitivity depends on the most sensitive species, and (2) protecting community structure protects community function. While the latter assumption is hardly questionable, the former needs further examination in light of the introductory statements to Chapter 3.

For many existing and most new substances, the pool of data on ecosystem effects is very limited; i.e., only short-term toxicity data are available as a rule. This implies the application of assessment factors that permit one "to predict a level at or above which the balance of probabilities suggests an environmental effect will occur. It is not intended to be a level below which the chemical is considered safe. However, again, the probability is that there will be no effects" [289]. When defining assessment factors, a number of uncertainties must be taken into account in attempting to extrapolate from mono- or oligospecific laboratory test systems to multispecies ecosystems: (1) intra- and interspecies variations, (2) acute to chronic toxicity extrapolation, and (3) extrapolation of laboratory data to field impact. Additional uncertainty results from the different testing methods themselves or interlaboratory variation in toxicity data.

When reviewing data from laboratory test systems the assessment factors of Table 17 are proposed. Instead of using assessment factors on the lowest-effect data, statistical extrapolation methods may be applied to a (relatively large) set of long-term data as an alternative approach. The underlying assumptions are [292]:

1) The distribution of species sensitivities follows a theoretical distribution function
2) The groups of species tested in the laboratory are a random sample of this distribution

This implies the use of no-observed-effect concentrations (NOECs) for identical parameters (e.g., reproduction) of the species considered [293], especially if only limited data from different species are available [294]. Normally long-term toxicity data are log-transformed and fitted according to the distribution function, and a prescribed percentile (e.g., 95 % [292]) of this distribution is used as a criterion. This means that the NOEC may be exceeded for 5 % of the species in the community. The validity of some of the above assumptions may be questioned (see also [294], [295]). First of all, it must be taken into account that for most compounds few longterm NOECs are available so that most tests on distribution functions have low power. Second, the NOECs available are not a random sample. Emans et al. [296] compared NOECs derived from multiple-species experiments for aquatic systems with extrapolated values [297], [298] and came to following conclusions:

1) Validation is rendered difficult by the lack of reliable data from multiple-species tests and long-term monospecific tests
2) Results from both statistical extrapolation approaches do not differ significantly
3) Results of the statistical extrapolation with 5 % confidence are in good agreement with results from (semi-) field tests

Table 17. Assessment factors for aquatic toxicity testing (after [289–291])

Toxicity data	Factor		
	EC	OECD	ECETOC∗
One short-term toxicity value: algae, daphnia, or fish		1000	
Short-term toxicity: algae, daphnia, and fish	1000 [lowest L(E)C_{50}]	100	200
Long-term toxicity: fish or daphnia	100 (NOEC)		
Long-term toxicity: algae, daphnia, and fish	10 (lowest NOEC)	10	5
Long-term toxicity: two species in two taxonomic groups	50 (lowest NOEC)		
Field or mesocosm toxicity	case-by-case evaluation		1

∗ ECETOC = European Chemical Industry Ecoloy and Toxicology Centre.

3.2.2. Testing Strategies for Terrestrial Ecosystems

Soil constitutes a central compartment of terrestrial ecosystems. Chemicals introduced into soil can be adsorbed on soil constituents or transformed by soil organisms; furthermore, they may be taken up by plants, washed out by rain or irrigation water, or evaporated in gaseous form. The extent of adsorption is controlled by various soil properties, including composition and content of organic matter, type and content of clay minerals, ion-exchange capacity, and acidity; it is also closely connected to the physical and chemical properties of the substance in solution (see Section 2.4.2). In view of this complex situation, the empirical knowledge of the behavior of environmental chemicals is still fairly limited, and the possible danger of excessive fertilizer or manure application, pesticides, and heavy-metal contamination of soils and crops has been recognized only in the last decades, mostly in relation to the agriculture use of sewage sludge or in connection with atmospheric deposition of organics or heavy metals.

Given the fundamental importance of soil for biological conservation, fertility, element fluxes, biodegradation of organic materials, and retention and filtration of groundwater, broad agreement exists as to the necessity of specific, use-oriented risk assessment procedures. As for risk characterization in aquatic ecosystems, the predicted no-effect concentration in soil ($PNEC_{soil}$) must be compared with the predicted environmental concentration in soil and subsoil (PEC_{soil}) as described in Section 3.1.4.

3.2.2.1. PNEC Estimates for Soil and Subsoil

Terrestrial Tests and Assessment Factors. A substance discharged into soil can have noxious effects on both the soil's physicochemical properties and its biocenoses. If the pore structure of a soil is affected by the chemical, the soil might silt up and be compacted; thus, the percolation rate is reduced considerably, the water balance is impaired (see Section 2.1.2), and the air supply is impeded. Since soil acts as a pH buffer system and a reservoir for bound substances, impairment of the soil adsorption capacity by xenobiotics can infer exhaustion of the buffer capacity. Impairment of microbial activity implies a reduction of the catabolic and metabolic capacity of the soil, which may lead to retarded liberation of nutrients and accumulation of mainly organic substances; this implies further effects on soil-dwelling organisms [35]. A chemical represents a risk to the soil compartment of an ecosystem if its concentration exceeds the degradation potential of the soil or if it changes the soil properties – in particular, the filtration, buffering, and transformation functions – in such a way that adverse effects result for the environment [299]. Thus, data on geoaccumulation as obtained in the framework of exposure assessment may give a first indication of possible changes in soil properties. The $PNEC_{soil}$ can be derived from the results of toxicity tests on soil and subsoil organisms by the application of assessment factors. If no ecotoxicological data are available for such organisms, the equilibrium partitioning method may be applied as a first approximation. It assumes that the bioavailability and therefore the toxicity of chemicals are determined by their concentration in the pore water of soil. The applicability of the method has been

tested less for soil- than for sediment-dwelling organisms; VAN GESTEL [300] has demonstrated its validity forearthworm toxicity for several chlorophenols, chlorobenzenes, and chloroanilines. Whether this also holds true for other compounds or species is questionable, however (e.g., lipophilic compounds or organisms that are exposed primarily via food).

For few existing chemicals, short-term terrestrial tests are available with microorganisms, earthworms, and higher plants; in addition, a long-term test is used with springtails. For new substances, two standardized short-term tests with higher plants and earthworms are required at level 1. If no acute tests are available, tests on primary producers, consumers, and decomposers should be applied for the preliminary stage of the concentration-effect assessment [301–304]. The Umweltbundesamt [290] suggests use of the same assessment factors for terrestrial as for aquatic ecosystems, depending on the type of investigations, (i.e., acute or long-term toxicity test) and the number of trophic levels studied (see Table 18).

Table 18. Assessment factors for terrestrial ecosystems (after [290])∗

Information available	Assessment factor
L(E)C_{50} for preliminary stage toxicity tests (e.g., acute toxicity to plants and earthworms or microorganisms)	1000
NOEC for one additional long-term toxicity test	100
NOEC for additional long-term toxicity tests for two species of two trophic levels	50
NOEC for additional long-term toxicity tests for three species of three trophic levels	10
Field data/data of model ecosystems	case by case

∗ The $\mathrm{PNEC_{soil}}$ is calculated on the basis of the lowest effect value measured.

Standardized long-term tests for earthworms [305] and for springtails [304] are available, both of which analyze effects on reproduction. The standardization of two long-term tests is close to completion: the test on staphylinids (Coleoptera) registers degree of parasitism, hatching rate, and reproduction [306]; the test on *Enchytraeus* (Annelida) can replace the reproduction test on earthworms [307]. VAN STRAALEN and VAN GESTEL [308], STAVOLA [309], and PEDERSEN and SAMSØE-PETERSEN [310] discuss test methods with various terrestrial species and different degrees of standardization.

Evaluation of Stress Tolerance of Soils as Ecosystem Compartments. To comply better with the exigencies of a provision-oriented environmental policy, the critical loads of soil with regard to nutrients, heavy metals, and xenobiotics require a generalized ecological evaluation, in addition to estimates of human exposure to contaminants in soil (see → Toxicology, Chap. 5.; → Soil, Chap. 6.2.). This implies the rational definition of soil standards that aim at sustaining appropriate physicochemical and biotic soil functions.

A recent approach of this type is based on the regionalized determination of geogenic and anthropogenic concentrations of potentially hazardous chemicals, and the assessment of different degrees of adverse chemical effects on soil and related biota [299] (see Table 19). Thus, the preventive threshold value C_{p} characterizes chemical concentration levels not affecting any essential ecological soil function. The C_{eff} value is indicative of first and low-level adverse effects and is defined by means of ecotoxicological test procedures and determination of the physicochemical behavior of xenobiotics in soil. By contrast, the C_{dis} value indicates long-lasting or permanent disturbance of essential biotic and abiotic soil functions. Among the extrapolation methods for determining ecologically relevant effect concentrations [293], [311–316], the last mentioned appears most appropriate. It defines a hazard concentration ($\mathrm{H}C_{\mathrm{p}}$) that ensures the protection of a certain number of soil-living animals. Thus, the approach is based explicitly on resilience considerations (see Section 2.1), using NOECs as reference values. The hazard assessment involves four steps:

1) Determination of at least five NOECs
2) Standardization of NOECs values with regard to a standard soil from at least three taxonomic groups according to the following equation

$$\mathrm{NOEC}' = \mathrm{NOEC}\,(L,H)\,\frac{R\,(25,10)}{R\,(L,H)} \tag{64}$$

where NOEC′ is the NOEC of standard soil; NOEC (L, H) ist the experimental NOEC

with given clay (L) and organic matter content (H); $R(25, 10)$ is the reference value of standard soil with 25 % clay and 10 % organic matter; and $R(L, H)$ is the reference value on the basis of the clay and organic matter content of the test soil.

3) Determination of a safety factor T in relation to the different sensitivity of indicator species

$$T = \exp\left[\frac{3S_{\mathrm{m}}d_{\mathrm{m}}}{\pi^2}\ln\left(\frac{1-\delta_1}{\delta_2}\right)\right] \tag{65}$$

where S_{m} is the standard deviation of ln NOECs; d_{m} is a factor dependent on the number of test species; δ_1 is the proportion of nonprotected species, related to defined hazard concentration (HC_{p}); δ_2 is the probability of overestimating HC_{p}; and T is a safety factor for NOEC average.

4) Based on this safety factor the hazard concentration HC_{p} is defined as

$$HC_{\mathrm{p}} = \frac{\exp(x_{\mathrm{m}})}{T} = \frac{\overline{\mathrm{NOEC}}}{T} \tag{66}$$

where m ist the number of test species; x_{m} the mean value of ln NOECs; and $\overline{\mathrm{NOEC}}$ the geometric mean value of NOECs.

The exemplary application of Equation (66) to cadmium and a test system of *Dendrobaena rubida, Lumbricus rubellus, Eisenia foetida, Helix aspera, Porcellio scaber, Platynothrus peltife*, and *Orchsella cincta* would yield an HC_5 (i.e., $\delta_1 = 0.05$) of 0.16 mg Cd per kilogram of soil. In comparison, the present A level of the Dutch "Leidraad Bodemsanering" is equivalent to 0.80 mg Cd per kilogram of standard soil.

As long as the C_{eff} value, defined by means of the above prodecure, is not exceeded, no essential reduction of ecological soil functions occurs and the long-term multifunctionality of soil is sustained. In contrast to this threshold, the C_{dis} value indicates a distinctly higher concentration of pollutants in soil that exerts long-lasting or irreversible effects on biotic and regulative soil functions. For assessment purposes, basically the same approach is foreseen as for the definition of C_{eff} (i.e., multispecies determination of HC_{p} with a p around 50). Unter these circumstances, neighboring ecosystems may also be affected due to export of primary pollutants or their metabolites. Thus, the C_{dis} value characterizes a threshold that necessitates protective or rehabilitation measures. Depending on both quality and intensity of land use, these may be quite different, including, e.g., limitations of crop production or reduction of fertilizer and pesticide application [299].

Complex Biotic Indicator Systems for PNEC Estimates. Toxic effects of chemicals in a biocenosis change according to the species composition of the community exposed to them. This is particularly important when a community is continually exposed to a concentration of a substance since its species are either least sensitive to this substance or adapted to it. Consequently, the effects of the substance on a selected laboratory test organism or a monospecific assemblage not previously exposed to that particular substance may be quite different. In consequence of these and other limitations of the aforementioned tests, artificial laboratory microecosystems (microcosms that simulate some of the characteristics of natural ecosystems) are more frequently used in toxicological studies [288], [317].

Model Ecosystem Approach. The model ecosystem approach uses physical models of natural ecosystems to simulate a selected subset of the relevant physical, chemical, and biotic characteristics of a potentially affected environment. These models may vary in complexity from a bacterial culture in a test tube to a net cage isolating a part of an ecosystem. Normally, the model ecosystem involves an aquarium or other small container in which soil, sediment, water, and several trophic levels of organisms are kept. Thus, METCALF and coworkers [318] studied the effects of chemicals in a terrestrial – aquatic interface to determine their potential to accumulate in food chain organisms and to degrade. Tests with the *Metcalf microcosm* have been standardized to permit comparison of different chemicals. Although this system does not allow for prediction of absolute concentrations of a substance expected or observed in a wide variety of actual environmental conditions, it has shown positive relationships among physical, chemical, and biotic properties, (e.g., water solubility and bioconcentration potential). However, it has not been used typically to determine rates of dominant processes, nor has it

Table 19. Complex ecological threshold values for soil quality characterization [299]

Natural background "clean soil"	Range of tolerable disturbance no further chemical stress	Range of permanent heavy disturbances changes in land use, hazard assessment, and restoration indicated
C_p	C_{eff}	C_{dis}
No reduction of ecological soil functions		
Multifunctionality: optimum range of ecological soil functions	first low-level adverse effects on ecological soil functions	long-lasting or permanent disturbances of essential ecological functions
No detrimental fluxes of chemicals	no detrimental fluxes of chemicals	detrimental fluxes of hazardous chemicals into neighboring ecosystems
Optimum conservation of species	almost complete conservation of species (HC_5)	species deletion (HC_{50})
Site-specific quasi-natural climax communities	$\longrightarrow$	possibilities of land use reduced
Any form of ecologically indicated land use possible	gradually increasing reduction of soil functions	biotic and abiotic soil functions reduced

sufficiently incorporated many of the dynamic properties found in other aquatic environments.

FREHE's *greenhouse approach* [319] is an example of microcosm research related to agriculture. Each microcosm, measuring $207 \times 193 \times 200\,cm^3$, was fixed on a lysimeter containing a soil mixture (loess loam, sand, and peat) with an earthworm (*Lumbricus terrestris*) population; an association of pea (*Pisum sativum*), vetch (*Vica sativa*), oat (*Avena sativa*), and mustard (*Sinapis alba*) was grown in it. The greenhouses were provided with ventilation and sprinkling systems permitting the application of di-(2-ethylhexyl) phthalate for testing purposes in aerosol form.

Studies in such small-scale laboratory systems are valuable tools to demonstrate some principles of concern in ecotoxicology and have to be included in the general knowledge of the fate of chemicals in natural large-scale ecosystems. They are indispensable additions to single-species experiments in order to more reliably evaluate the influence of interspecific interrelationships on the toxic potential of compounds. An example is zinc toxicity with respect to marine diatoms and dinoflagellates, which, in the majority of cases, proved to be definitely more pronounced in five-species tests than in monospecific cultures [320]. Hence, an abbreviated model ecosystem approach may prove useful in environmental concentration – fate studies by providing data on the rate constants of some of the processes that govern the transport and transformation of chemicals. Thus limited-scope model ecosystems contribute to determine whether a mathematical model accurately or approximately predicts concentrations in the various environmental compartments included in the model ecosystem. Expanded types of microcosms may be envisaged to include a substantially higher amount of that variety of physical, chemical, and biotic properties that a chemical is likely to encounter in the real environment. In terms of structural diversity, these comprehensive, and consequently more expensive, *mesocosms* lead over to biocenotic experiments under open-air conditions, which constitute the highest assessement level possible.

Biocenotic Experiments. Individual *populations* display marked changes in abundance as a direct consequence of the exposure pattern and an indirect consequence of the induced variations of intra- and interspecific competition and resource availability. Thus, almost all collembolan species exposed to cypermethrin displayed a longer increase in population density after an initial reduction, followed by a secondary decrease, probably due to excessive exploitation of food resources or an increase of predators [321]. In numerous experiments, complete annihilation of species was the exception; recedent taxa were mostly affected. Yet in a few cases, populations with dominant species were almost completely suppressed (e.g., the predatory mite *Rhodacarellus silesiacus* and the collembolan species *Isotomina bipunctata* on experimental plots treated with aldicarb [322]). Also, nontarget organisms experienced changes in their abundance spectra that lasted for several years [323].

At the *community level*, chemicals nearly always induce changes in the abundance spectra,

whereas changes in species composition occur less frequently, particularly as a result of persistent multifactorial stress [324], [325].

Ecosystem PNEC Assessment. Integral PNEC indicators at the *ecosystem level* are

1) Fluxes of macro- and micronutrients (K, Ca, Mg, N, P, S and Fe, Mn, Cu, Zn, Mo, B, Cl)
2) Duration of biochemical cycles
3) Energy flux rates and entropy production of phytocenoses
4) Changes in biodiversity and population dynamics
5) Structure of trophic networks or experimental food chains

Examples of the first groups of indicators are the influence of pentachlorophenol (PCP), 2,4-D, 2,4,5-T, and aldicarb on the nitrogen balance and litter degration of beech, pasture, and fallow ecosystems [326], [327]. In either case, degradation was impeded and the nitrogen content of the litter bags reduced. Shortly after application of the chemicals, the release of inorganic nitrogen compounds increased considerably at the expense of microflora and fauna. Furthermore, the retention capacity and the availability of many nutrients were diminished, and these effects lasted for more than four years depending on the chemical character and application rate of the compounds tested.

3.2.2.2. Complex Assessment and Modeling of Vegetation Damage

Pollutant gases such as sulfur dioxide and nitrogen oxides are frequently emitted in combination and normally with other pollutants such as soot and heavy-metal particles; in many places, photooxidants are emitted simultaneously. In these cases, the effects of combinations of pollutants are not simply the sum of the effects of individual components, but the relative concentrations of components or the specific sensitivity of the plants to one of them may determine the response. Thus, pollutants in combination may display antagonistic (reduced), additive (sum of individual pollutant effects), or synergistic (superadditive) effects.

In the past, most experiments on exposure to combinations of pollutants were carried out under laboratory conditions using higher concentrations of gases than are typical in the field. Newer fumigation techniques, for instance open-top chambers [328] or field fumigation systems [329], have now enabled the exposure of plants under field conditions with increasingly realistic concentration ranges. These experiments indicate that pollutant combination effects depend on pollutant concentrations; SO_2 and O_3 are often antagonistic at levels where the individual gases cause severe leaf injury, while superadditive effects predominate at lower concentrations (i.e., $SO_2 < 140\,\mu g/m^3$, $O_3 < 100\,\mu g/m^3$), particularly near the threshold dosage [330]. In addition, the injury symptoms for SO_2 and O_3 in combination are not a simple mixture; frequently, the symptoms of one pollutant occur more clearly or earlier than those of the other [331].

With regard to combinations of NO_2, SO_2, and O_3, effects were produced in many plants by lower concentrations of NO_2 and the other gases than if they acted alone, especially at the lower exposure levels [332], [333]. Synergistic effects of NO_2 in combination with SO_2 or O_3 apparently result from a decrease of the nitrate and nitrite reductase activities. While the latter tend to rise in response to NO_2 acting on its own, activation of these reducing enzymes is limited or even suppressed by the simultaneous presence of SO_2 or O_3 [334]. This adverse effect is further enhanced by the formation of free radicals. An inhibitory influence on the regulation of transpiration occurred at less than $20\,\mu L/m^3$ $SO_2 + 20\,\mu L/m^3$ NO_2 [335]. The combination of NO_2 with O_3 is likely to endanger vegetation more than $NO_2 + SO_2$ in combination and should receive greater attention since these pollutants form essential components of photochemical smog. The threat to vegetation may increase still further if all three pollutants interact simultaneously [332], [333], [336], [337].

Combination effects, however, also depend on the temporal order in which the pollutants affect the plants. If they are first exposed to NO_2 and thereafter to SO_2, the usual SO_2 effects are reduced, while the opposite sequence causes superadditive effects because SO_2 affects nitrite reductase [334], [338]. Attention must also be drawn to the combination of gaseous SO_2 with acid precipitation; the effects of this combina-

tion are discussed in connection with the new types of forest damage.

Critical Levels. In conclusion, and with some reservations resulting from the above remarks, critical levels for short-term and long-term exposures may be defined. In view of the fact that most horticultural and agricultural plants do not show adverse effects at *sulfur dioxide concentrations* $<30\,\mu g/m^3$, while particularly sensitive species of trees, moss, lichens, and bushy and grassland vegetation are adversely influenced by concentrations of ca. $20\,\mu g/m^3$, the critical level for SO_2 acting on its own is to be set at $20\,\mu g/m^3$ ($\approx 0.007\,mL/m^3$) as the annual mean value. Experimental fumigation trials that indicate first adverse effects from $70\,\mu g/m^3$ SO_2 (≈ 0.025 ppm) for cultivated plants form the basis for setting the short-term value at this concentration [331].

Leaf necroses were the predominant effects of short-term, mainly single exposures of plants to $>1\,mL/m^3$ *nitrogen dioxide*; lower concentrations caused alterations in photosynthesis and respiration as well as in organelle ultrastructures. The particular sensitivity of plants at night must also be taken into account, and the fact that high NO_2 concentrations are often associated with high NO levels. For long-term exposures, a seasonal differentiation of sensitivity is indicated. Thus, for summer, when the physiologically more active plants can rapidly metabolize NO_2, a half-year mean of $0.03\,mL/m^3$ appears tolerable. In winter, however, when plants are particularly sensitive, a half-year mean of $0.02\,mL/m^3$ must not be exceeded to protect both short-lived plants and long-lived arboreal flora.

Experimental investigations of *ozone damage* [337] permit definition of the following critical levels for the protection of vegetation against O_3 as a single pollutant. For longer-lasting exposures, $50\,\mu g/m^3$ ($\approx 0.025\,mL/m^3$) O_3 appears indicated as a vegetation period average (composed of 7-h daylight mean values).

For *NO_2 in combination with O_3 and SO_2*, the World Health Organization has adopted an Air Quality Guideline of $30\,\mu g/m^3$ NO_2 as the arithmetic annual mean for areas in which SO_2 and O_3 may occur in annual and vegetation period means of up to $30\,\mu g/m^3$ SO_2 and $60\,\mu g/m^3$ O_3 [333]. However, nitrogen oxides do not only have direct effects, they may also affect plants indirectly via the soil, with additional nitrogen input greatly endangering nutrient-poor plant formations such as heath and moor communities. An amount of $10\,\mu g$ NO_2 per cubic meter may suffice to damage the particularly sensitive ombrotrophic mires [339].

On the basis of exposure – effect relationships as determined for a variety of plants of widely differing sensitivity by various authors, Posthumus [340] deduced the following critical levels for *ammonia*:

$100\,\mu g/m^3$ ($\approx 0.14\,mL/m^3$) for monthly mean concentration
$600\,\mu g/m^3$ ($\approx 0.86\,mL/m^3$) for 24-h mean concentration
$10\,mg/m^3$ ($\approx 14.3\,mL/m^3$) for 1-h mean concentration

Impacts on Forest Productivity. Since the 1970s the indirect effects of acid precipitation on forest trees and crops has been a major area of both scientific and economic concern. In Germany, forest decline attributed to flue gases, particularly SO_2, was described in the neighborhood of industrial plants more than a century ago. The situation did not change essentially until the late 1960s, when a new type of forest injury became evident that was no longer related to local emitters but occurred to an increasing extent in presumably clean air areas far away from conurbation and industrial centers [341–345]. In the mid-1970s, severe dieback of silver fir (*Abies alba*) was observed in southern Germany. In the early 1980s, other conifers, especially Scotch pine (*Pinus sylvestris*) and Norway spruce (*Picea abies*) showed similar symptoms over rapidly increasing areas, and deciduous species such as beech (*Fagus sylvatica*) and oak (*Quercus robur*) have recently been affected. According to the 1985 damage inventory, 52 % (i.e., 3.8×10^6 ha) of the forest areas in the 58 growth districts of the Federal Republic of Germany were injured. Level 1 of damage (reduction of vitality) characterizes about two-thirds of this portion, while medium to high damage (levels 2 – 4) occurs on 19 % of the forested area [346].

Comprehensive studies [347–350] show that the lack of nutrients, climatic factors [351], mistakes in forest management, infections, and pests

may play an important role in the present complex forest diseases; but a rapidly growing number of findings indicate that the above anthropogenic air pollutants, and possibly others such as triethyl lead or nitrophenols [352], [353], and related soil acidification are the essential direct and indirect causes of damage [328], [354–357].

At the cellular level, pollutants may lead to a disturbance of photosynthesis and respiration and the following primary and secondary metabolisms. In some cases, impairment of photosynthesis occurs before visible damage can be observed [358]. At the same time, photooxidants and acid rain cause weathering of cuticular structures, destruction of membrane systems, and leaching of nutrients from leaves. Quantitative and qualitative changes in photosynthesis [359] lead to reduced primary production, increased respiration, and a changed assimilate allocation to the root – mycorrhiza system, stem, branches and leaves, and also to the reproduction and phytogenous defense system. Such stressed trees emit unsaturated hydrocarbons such as ethylene, isoprene, and terpenes, which react with secondary pollutants (e.g., ozone) and highly phytotoxic tertiary pollutants in the immediate neighborhood of the plants. Weakening by reduced assimilate allocation to the roots leads to reduced uptake of nutrients from soil that has already been disturbed by acidification (i.e., impoverished in potassium and magnesium).

Murach [360] determined a calcium deficiency in the roots of declining spruce and fir, but the same levels of aluminum as in healthy trees; Rehfuess et al. [361] noted magnesium and possible calcium deficiencies by foliar analyses even on base-rich soils. Contrary to Ulrich's [362], [363] contention that a change in fine root biomass is paralleled by toxically high Al : Ca ratios, Rehfuess points out that the two phenomena are not necessarily synchronized, so that marked decreases in fine root biomass can precede the increase in soil solution aluminum.

Mineral deficiency due to leaching and soil acidification is frequently coupled with a relative surplus of nitrogen with respect to assimilated carbon as a consequence of enhanced deposition of nitrate and ammonia and the intensity of subsequent nitrification processes. Kriebitzsch [364], who studied nitrification in many types of acidic forest soils, divided them into groups A, B, C, and D. In group A, no nitrification occurred and ammonium was the only nitrogen source. In soil of groups B and C, partial nitrification occurred, while group D soils had complete nitrification. Former heathland soils in Germany now cultivated with various *Pinus* species and *Pseudotsuga* belong mainly to group A, where the nitrate level is low, whereas the ammonium concentration is high.

Quantitative and qualitative changes in the living biomass of forest trees will bring about changes in the food web of the forest ecosystem; the population of some consumer (e.g., insects) or decomposer organisms (e.g., fungi) may grow explosively while others are completely suppressed. The disturbance of soil biocenoses may then induce a reduced litter decomposition that leads to a further shortage of minimal nutrients. Trees subject to these stress factors are in general extremely sensitive to secondary damage by frost, drought, or insect infestation.

Visible *injury to crops* as a result of ambient acidic precipitation has not been reported from modern high-productivity agrarian ecosystems. Therefore, attempts to evaluate impacts of acidic deposition must be based on simulated precipitation in field experiments or controlled environments. Yet most of the crop cultivars studied in the field and the crop varieties studied in controlled environments exhibited no effect on growth or yield as a result of exposure to simulated rain usually up to ten times more acidic than ambient [365]. Likewise, out of five cultivars of soybeans studied, only one exhibited reduction in yield [366]. Genetic variations, possibly in combination with characteristics of the soil or simulated rain applied in these experiments, may account for the observed variability.

3.2.2.3. Statistical Analysis of Forest Dieback

Descriptive or static models of forest decline are analyses of the spatial correlation pattern of site qualities and damage levels [348], [367] that corroborate the importance of pedogenic nutrient supply and acidification processes for forest decline. Figure 41 illustrates, on the basis of comprehensive cross-tabulations of several hundred German stands, the extent of forest damage in terms of relevant site factors. The standardized damage level S (i.e., proportion of

injured : unaffected forest area) correlates best with the pedogenic nutrient supply, frequency of fog situations, and elevation, while the correlation with other site factors is also significant on the 99.9 % level although of little statistical relevance; $S = f(Sq)$ is a monotonous function, while $D = f(Nf)$ has a marked maximum. Thus, stands on members of the ranker, cambisol, and podzol soil groups with pH <4, marked nutrient deficiency, and concomitant reduction of buffering capacity down to the aluminum and iron ranges are most liable to dieback. Among airborne pollutants, SO_2 is particularly important. In combination with other pollutants, its effect on both vegetation and soil is enhanced by fog (contingency coefficient after Pearson $C = 0.53$). The amount of sulfur deposition is controlled mainly by precipitation ($C = 0.80$). Comparison of the pH and sulfur deposition curves ($C = 0.89$) summarizes the major influence of gaseous and particulate pollutants on forests as a result of the above mechanisms. Their inherent complexity implies the recognition that critical levels for tolerable pollutant concentrations can be defined adequately only with regard to the entire set of concomitant stress factors affecting a plant community.

A more sophisticated analysis of the data of forest decline monitoring programs can be brought about by the CHAID approach (see Section 2.1.1.1) [103], [368]. CHAID divides the total data set successively into subsets that are, at each level of partitioning, characterized by the very variable that best explains the distribution and intensity of damage. Thus, the explicative value of different combinations of decline-inducing factors can be tested on high levels of statistical significance. A further advantage is the easy interpretability of the CHAID dendrograms.

Thus, a dendrogram of forest decline of about 500 stands in North Rhine-Westphalia clearly indicates the predominant role of the factors age, crown density, and composition of stand as boundary conditions of forest decline, while climatic factors such as annual precipitation and anthropogenic pollutant gases play a distinctly lesser role. These results are corroborated by comparable findings in other parts of Germany [103].

Dynamic Models of Forest Dieback. Simulation models of forest decline have to deal with two types of change – (1) change in complexity through increasing or decreasing differentiation, and (2) adjustment to extrasystemic changes. Negative and positive feedback processes can be correlated with systemic continuity or discontinuity, respectively. Continuity results when deviation-correcting mechanisms operate to ensure that structure and function are kept viable within the given parameters of the system. Quantization occurs when deviation is amplified to the point at which no deviation-correcting mechanism can prevent rupturing of the basic systemic framework (i.e., when resilience mechanisms are no longer able to contain and canalize the energies and thrust that have been generated). The process alters the relationships of the system to its environment, creating new spatiotemporal, structural, and functional boundaries – in short, the system is transformed to a new level of internal organization and environmental integration. Therefore, and specifically with regard to forest decline, models must employ system concepts to explain the circumstances in which quantization can occur from one developmental stage to another. Hence, they have to account for both systematic levels of biocenotic organization and cybernetic processes that demonstrate (1) systemic self-stabilization within a given organizational level and (2) systemic transformation resulting in a biocenotic quantum jump across an environmental frontier.

Models with Nonlinear Dose – Effect Relationships. Following models of reduced photosynthesis and leaf formation, and increased leaf aging and shedding under air pollution stress [369], [370], Kohlmaier and Plöchl [371] developed a more comprehensive model concept for damage of Norwegian spruce. It includes the root system with reduced nutrient uptake and higher feeder root turnover, thus coupling the canopy and the soil root system. Reduced photosynthesis and changed assimilate allocation are simulated during the entire exposition to airborne pollutants, which may be a part of or the whole life span of a tree. Assimilate demand and supply have a hierachic structure with regard to, e.g., respiration, growth of foliage, roots, and living wood. The effect of an air pollutant on leaves and roots depends on both the

Figure 41. Forest decline as related to selected site factors
$\hat{S}$ = Ratio of damaged : undamaged forest area; A = Altitude (m); Nf = Number of foggy days; Sq = Soil qualitiy (nutrient supply); P = Porosity (percentage of pores >50 µm); F = Plant available field capacity (mm); pH = Percentage frequency of acid rain (i.e., pH <4.5); S-dep. = Sulfur deposition

specificity of instantaneous effects and the cumulative effects during the entire exposure time involving elimination and repair mechanisms of the plant. The complicated interaction pattern of these response mechanisms normally results in nonlinear dose – effect relationships with respect to concentration and accumulated pollutant and damage level of the plant. During one time step, the model first calculates the photosynthesis rate as dependent on external factors such as light intensity and air temperature, and internal parameters such as photosynthetic leaf efficiency; water uptake by roots is the limiting factor. Pollutants can enter the system by two different paths (i.e., leaves or needles and roots); in the first case, the photosynthetic efficiency of a particular needle age class is reduced; in the second, fine root turnover and consequently assimilate demand are increased. The momentary pollutant flux into the leaf is described in terms of gas exchange between the intercellular air and the ambient air by Fick's first law:

$$I_{\mathrm{in}}^{\mathrm{leaf}} = (c_{\mathrm{a}} - c_{\mathrm{i}}) / r_{\mathrm{ai}} \tag{67}$$

where the flux $I_{\mathrm{in}}^{\mathrm{leaf}}$ is proportional to the concentration difference $(c_{\mathrm{a}} - c_{\mathrm{i}})$ between ambient

and intercellular air, and r_{ai} is a specific resistance factor for a particular pollutant. The corresponding flux per unit canopy or unit ground area is then obtained by multiplication with the leaf area index LAI. For the boundary condition $c_{\mathrm{a}} \gg c_{\mathrm{i}}$ Equation (67) reduces to

$$I_{\mathrm{in}} = (r_{\mathrm{ai}}/LAI)\, c_{\mathrm{a}} = u_{\mathrm{dep}} c_{\mathrm{a}} \tag{68}$$

which is approximately equivalent to the dry deposition rate, with u_{dep} being the deposition velocity.

The pollutant load in the leaf or at its surface may be assumed to be eliminated either by physical processes (e.g., litterfall), by transport to other parts of the plant, or by metabolic processes. It appears more appropriate, however, to model the elimination process according to Michaelis – Menten kinetics of the type

$$d\bar{c}_{\mathrm{i}}/\mathrm{d}t = u_{\mathrm{dep}} c_{\mathrm{a}} - k_{\mathrm{out}}\, \bar{c}_{\mathrm{i}} / \left[1 + (\bar{c}_{\mathrm{i}}/K_{\mathrm{c}})\right] \tag{69}$$

where $\bar{c}_{\mathrm{i}}$ is the concentration per unit ground area and k_{out} the characteristic elimination constant, while the other symbols have the above meaning. The mode of interaction and the effect of a pollutant inside the plant are likely to be specific for the particular pollutant j. In the simplest case, the effect, above the specific no-effect level, will be proportional to the interior concentration $\bar{c}_i^{\mathrm{j}}$:

$$eff^{j}(t) = a_j\, \bar{c}_i^{j}(t) \tag{70}$$

where a_j is a specific effect constant relating to a particular process (e.g., photosynthesis). The effect variable *eff* (t) may be composed of linear and higher-order terms of n interacting species:

$$eff(t) = \sum_{j=1}^{n} a_j \bar{c}_i^{j}(t) + \sum_{j=1}^{n} \sum_{k=1}^{n} a_{jk} \bar{c}_i^{j} \bar{c}_i^{k} \tag{71}$$

where synergetic effects are included in the second term with $j \neq k$.

According to Bossel et al. [370], the effect variable affects the leaf senescence function

$$ALT(t) = 0.1\,[1 + eff(t)] \tag{72}$$

with $0 \leq eff \leq 1.5$ and $0.1 \leq ALT \leq 0.25$, implying that the value 0.1 is the natural senescence rate without pollutant damage. The senescence rate influences the number of needle age classes:

$$NJ = 0.8/ALT(t) \tag{73}$$

and both determine the leaf's photosynthetic efficiency. Hence, the photosynthetic efficiency of a particular needle age class is

$$E(N) = 1 - ALT(t)\,[(N-1) + TJ] \tag{74}$$

where $0 < TJ < 1$ characterizes the season and $1 < N < J$ the age of a needle class.

The average photosynthetic efficiency is then expressed by

$$EFF = \sum E(N)\, L(N)/LEAF \tag{75}$$

where $L(N)$ is the leaf mass of a particular needle age class and $LEAF$ the total leaf mass. In unaffected systems, EFF ranges between 0.55 and 0.65 [371].

Acidification of soil and related leaching of mono- and bivalent cationic nutrients leads to higher feeder root turnover rates while a gradual loss of feeder root mass occurs. Following a titration curve of a buffered chemical system, this effect may be described by a logistic curve of the type

$$W_{\mathrm{to}}(t) = f[W(t)] = W_{\max} / \left[1 + F_k \left(3^{-Klt}\right)\right] \tag{76}$$

where $W(t)$ is the accumulated pollutant at time t; $W_{\max}$ the maximum accumulation; F_k the correction factor $(W_{\max} - 1)$; K the buffer constant; l the constant input; and $W_{\mathrm{to}}(t)$ the fine root turnover factor at time t [370].

This supply – demand model of photosynthetic efficiency and assimilate allocation appropriately describes the decline of a forest ecosystem under the influence of chronic air pollution stress. It clearly indicates that nonlinear effects may drastically accelerate the observed dieback phenomena, but more experimental data on both the biochemical and the physiological levels are required to better account for the combined effect of two or more pollutants [55], [372–374].

Time Series Analysis and Mapping. A common feature of the various methods of time series analysis of dynamic systems such as ecosystems is that they involve the observation of a complete set of state variables. This may constitute a major drawback in studies of empirical systems whose inherent dynamics are not known a priori. Under these circumstances, however, use can be made of the fact that in

dynamic systems with a finite number of state variables, information on the momentary value of all state variables can be replaced by information on the recent history of a part of the variables. GROSSMANN et al. [375] therefore used time series analysis in combination with geographic information systems (GISs) to develop a scenario that describes forest damage in sequential form by means of maps. A geographic information system is a computer hardware and software system designed to collect, manage, analyze, and display spatially referenced data. Geographic information systems are emerging as the major spatial data-handling tools for solving complex natural resource planning problems, and the use of GIS technology has revolutionary implications for conducting research and presenting research results.

The GROSSMANN et al. approach POLLAPSE is a combination of dynamic models writing information into the data bank of a GIS, which thus produces a time series of maps of forest growth or damage [375]. These maps can be compared with the actual development so that deviations become readily discernible. The hypotheses underlying this type of regionalized modeling are

1) Photochemical oxidants cause foliar damage, and subsequent attack of airborne pollutants leads to leaching, eventually resulting in nutrient deficiency [376]
2) Ulrich's soil acidification hypothesis [362]
3) A combination of the two preceding assumptions

The predictive quality of these hypotheses was tested in the Pfaffenhofen area (Bavaria) on the basis of 462 forest stands, and the POLLAPSE methodology showed that the combined hypothesis (3) yielded the relatively best interpretation of forest damage phenomena observed in terms of both spatial pattern and degree of damage. The above methodology of time series analysis and mapping also offers excellent possibilities for the management of forests or other biotic systems as a base for sustained viability.

3.2.3. Impact of Xenobiotics on Aquatic Ecosystems

Xenobiotics released to aquatic environments have a great impact on biocenoses inhabiting streams, wetlands, and lakes. This adversely affects not only the respective aquatic ecosystems, but also humans who are in contact with this water. Aquatic organisms show how far-reaching consequences can be caused by effects that are difficult to detect on a short-term scale and therefore easily overlooked. Similar to effects on aquatic biocenoses, in most instances the effects of xenobiotics on humans cannot be recognized, not only because the necessary analyses cannot be made, but also because small, difficultly detectable effects can grow into major and irreparable population damage. The following describes how difficult it is to foresee the effect of a chemical on an aquatic ecosystem merely from (easy to make) short-term tests. This is a warning that care for human health and life means that society cannot wait until some clearly seen negative effect is proved beyond any doubt but must react on early warnings obtained by sensitive methods. For more detailed information, see [56–64].

Figure 42. Food chains or food webs as the organization of organisms within an ecosystem according to food selection; arrows indicate directions of nutrient flow

3.2.3.1. Approaches and Methods of Studying the Impact of Xenobiotics on Aquatic Life

Aquatic life is organized into several hierarchic levels (Fig. 9 in Section 2.1.4):

1) Individual organisms
2) Monospecific populations
3) Communities of different species inhabiting the same environment, e.g., the pelagic communities freely swimming in water and benthic communities inhabiting the bottom of rivers and standing waters (ponds, lakes, reservoirs)

4) Ecosystems with their nonliving components interacting with organisms; within an ecosystem, organisms are organized into food chains (or more exactly, food webs) according to their selection of food items (Fig. 42)

Detection of the effects of xenobiotics is performed at all hierarchic levels of biological organization. In addition to this organizational hierarchy, a hierarchy of time scales of the effects can be distinguished, from very short ones measured in minutes up to very long ones measured in human generations [377], [378].

Methodology. The most common approaches to detect the impact of xenobiotics on aquatic life are listed below:

1) Classical toxicity tests on test individuals or cultivated populations of aquatic organisms to detect short-term lethal effects
2) Methods for detecting longer-term sublethal effects on test individuals and populations
3) Methods for detecting genotoxicity
4) Use of biomarkers, a relatively new approach for detecting stress effects of long-term exposure of individual organisms living in contaminated environments
5) Microcosm and mesocosm studies
6) Monitoring of long-term consequences of contaminants in nature by following the species diversity and loss of sensitive species in biocenoses and ecosystems

Other approaches are, e.g., predictions of toxicity based on molecular structure of the respective substances using quantitative structure – activity relationships (QSARs, see, e.g., [10], [220]), and tests for changes of morphologic or morphometric characteristics of organisms and detection of pathological individuals.

Classical Short-Term Toxicity Bioassays. Water organisms employed for these tests are usually some species of easily cultivated algae, water flies, and fish (see Section 3.2.1). Benthic, bottom-dwelling organisms commonly used are worms of the family Tubificidae living in the bottom mud of streams and lakes that are fairly polluted with organic matter of natural origin. In the simplest version, the tests consist of adding different concentrations of xenobiotics to jars (aquaria) containing the respective organisms and determining the time until half of the population dies (LC_{50} or LD_{50}). Recently, much care has been taken to standardize aquatic toxicity tests to maximize their major advantage – the rapid comparative evaluation of many xenobiotics [65].

Long-Term Sublethal Effects of Xenobiotics. In the aquatic environment, long-term sublethal effects are studied by measuring different reactions of test organisms. An example is the behavioral test with the freshwater bivalve mollusk *Dreissensia polymorpha* [379]. Its filtering rate, which is determined anemometrically in this test, represents a vital function, providing food and therefore vitality, growth, and reproduction of the organism. Detection limits of long-term sublethal tests are several orders of magnitude higher than those of short-term toxicity tests.

Genotoxicity. Compounds such as diethylstilbestrol that disrupt the endocrine systems of fish, wildlife, and humans were found to induce large-scale dysfunction at the human population level [66] by causing genetic and reproductive changes. Genotoxicity is studied by observations of the offspring of the affected population.

Determination of Biomarkers. Measurements of body fluids, cells, or tissues are carried out that indicate in biochemical or cellular terms the presence of contaminants or the magnitude of the host response [63]. Examples are, e.g., determination of marker enzyme activity in cells of target tissues, serum enzyme activity, appearance or loss of reaction products of an enzyme; major changes in the concentration of a cellular component such as glycogen, fat, mucus, or metallothionein; and measurements of damage to DNA.

Microcosm and Mesocosm Studies (see Section 3.2.2.1). Microcosms are laboratory model ecosystems consisting of mixed natural populations of organisms transferred from nature to a laboratory jar or aquarium, sometimes an arrangement that imitates a stream. Mesocosms are of the same origin, but of much larger volume and usually kept outdoors in their natural environment (e.g., [59], [380–382]). When xenobiotics are added, the changes in some common properties are measured (e.g., species composition, diversity, photosynthesis, or respiration).

Studies of Changes in Structure and Function of Communities and Ecosystems. Toxic chemicals can affect independently both the structure and the function of aquatic ecosystems. Low levels of perturbation may cause changes in community composition or structure without a change in function. Alternatively, a process, the rate of which is changed by stress (such as respiration or photosynthesis), may be reduced under sublethal stress, but the community structure is left intact. According to [383], the most predictable changes seem to be the disappearance of sensitive species from communities under environmental stress.

The integrated bioindicator approach currently gives the best results. It involves monitoring a suite of selected exposure and effects indicators at several levels of biological organization from the biomolecular to the community level [63], [384].

Critical Evaluation of the Above Approaches to Aquatic Ecosystems. For aquatic environments, *short-term lethal toxicity tests* have many advantages, as well as many disadvantages. Their major advantage is the ability to rapidly compare the relative toxicity of specific chemicals or specific mixtures. The limitations become particularly obvious when trying to use their results for higher levels of biological organization in the aquatic ecosystem. Thus, they do not account for the effects of

1) Chemical speciation in the environment
2) Kinetics and hysteresis in sorption of chemicals to sediments
3) Bioaccumulation through the food chain from the lowest level of algae and plants to the highest level of fish
4) Modes of toxic action on survival, growth, and reproduction of individual species populations

For aquatic sediments, an additional inadequacy is that sediment toxicity tests often rely on equilibration of chemicals in a sediment – water mixture or employ benthic organisms whose survival, growth, or reproductive success may depend not only on the presence of the toxicant but also on physical characteristics of the sediment.

The application of results of (laboratory) toxicity tests to natural populations is especially risky for the following reasons:

1) The way in which laboratory organisms are exposed to pollutants differs from exposure in the environment
2) Laboratory tests deal with single chemicals, and organisms are exposed to complex mixtures in the environment
3) Criteria for effects in the laboratory are not important functional endpoints in population and systems dynamics

The inadequacy of short-term tests for the aquatic environment may be shown by conclusions drawn from careful monthly bioassay results with the survival and reproduction of a water fly (*Ceriodaphnia*) and larvae of fathead minnow. These indicated that the effluent of an energy plant at Oak Ridge (Tennessee) causes no observed effect. However, community surveys demonstrated clear effects on diversity and species richness downstream of the power plant [63].

The use of *biomarkers* is more relevant to conditions in nature than acute toxicity methods. Biomarkers provide evidence of exposure to rapidly metabolized contaminants and in this way integrate pharmacodynamic and toxicological interactions. Correlations between biomarkers of exposure and ecological effects are expected to be better than those between populationmonitoring parameters and indicators of exposure.

Observations in nature can be performed only in rare instances when the concentration of the xenobiotic in nature is increased for a prolonged period. These observations cannot be used for testing new materials. Therefore an integrated system of xenobiotic hazard evaluation has been developed (see Sections 3.2.1, 3.2.3.4).

3.2.3.2. Behavior of Xenobiotics in the Aquatic Environment and their Influence on Aquatic Organisms and Indirectly on Humans

A chemical of potentially xenobiotic character follows a complicated flow from production site to the environment, as shown in Figure 43. The situation in fresh water depends not only on the direct emission of the respective chemical to the water body but also on its emissions and fates

in soil and groundwater (both associated with vegetation growth and decay), on the chemical and biological processes in the water body, and on the bioaccumulation in different organisms of a food chain. Environmental processes connected with local hydrometeorology, with precipitation and flow, and with temperature and light conditions modify the fate of xenobiotics. Figure 44 illustrates the behavior of hydrophobic xenobiotics in standing waters, particularly the exchange between the pelagic and benthic environment (i.e., between water and sediments). The participating major processes are shown: sedimentation, resuspension, and mud – water exchange. For hydrophilic xenobiotics, another important process is bioaccumulation (i.e., accumulation inside the organism's tissues and organs, mainly in fat and liver). In addition to these processes of an individual chemical compound, complex interactions occur between different chemical species in nature.

Many organic contaminants are readily taken up and *bioaccumulated* by aquatic organisms [61], [68] if the chemicals are dissolved in water. The bioavailability is much lower if the same compounds are sorbed to soil or sediment particles. Many toxic chemicals do not bioaccumulate but rather are metabolized. In many cases the metabolites are more toxic than the parent compounds present in the environment. Bioaccumulation, the process by which a substance is taken up by an aquatic organism from water and through food, is found to depend strongly on the size (weight) of the respective organisms (see, e.g., for pesticides [56], [387]). This is due to the dependence of most physiological processes on size (e.g., [59]). Biomagnification within aquatic food chains (i.e., the increasing concentration of toxic substances in higher organisms) was found important only for some chemicals (e.g., DDT [388]).

Humans are affected by the processes in water in different ways, as a result of their direct and indirect contact with water, but also through air, soil, and food. Large differences exist in the biological availability of contaminants associated with different environmental media, as well as individual and species-specific differences in pharmacodynamic disposition.

In most instances, one thinks of direct effects of the xenobiotic on organisms. However, recent ecological findings demonstrate that in nature the indirect effects are more important [389]. They are caused, e.g., by changes in food composition when some organisms become rare or disappear because of toxic effects and by changes in competition and other possible relations between organisms. An easily understandable example is the eradication of an aquatic weed species. Indirectly, this will cause a complete change of abiotic conditions not only for other species that depend on the weed directly, such as invertebrates living on it, but also for fish species finding their shelter.

Adaptation. Organisms are capable of adapting to the effects of xenobiotics to a certain degree, and this can have both positive and negative effects on individual organisms (including humans) and on the total environment, as well as on environmental management. Adaptive acquisition of degradative abilities for some organic compounds or of resistance to heavy metals has been demonstrated for bacteria in laboratory ecosystems [390]. Such an adaptive response may be caused by different molecular and biochemical processes: (1) induction of specific enzymes in members of the community, resulting in an increase in the observed degradative capacity of the total community; (2) growth of a specific subpopulation of a microbial community able to take up and metabolize the substrate; and (3) selection of mutants that acquire altered enzymatic specificity or novel metabolic activities at the onset of exposure of the community to the introduced compounds.

The *negative effects of adaptation* may be exemplified by pests (e.g., insects or weeds) in the framework of eradication programs [67]. In West Africa, the widespread parasitic disease filariosis is caused by the *Filaria.* This parasite is transmitted to humans by blackflies. To eradicate the flies, the organophosphate Temephos was applied on a large scale in about 18 000 km of rivers in the region during 1974 – 1980. However, resistance to this xenobiotic developed soon in one region and spread rapidly. Therefore, other means of eradication were sought that would act more persistently and not show the negative effects of the insecticide on other organisms in the rivers, since Temephos causes up to 100 % mortality of many insect species living on the river bottom. No toxicity to fish was observed. However, the insecticide accumulated in fish tissues,

Figure 43. Schematic representation of the flow of a chemical from production to the environment (after [385])

which may have negative effects on humans that consume the fish.

In addition to the use of another more toxic organophosphate (chlorophoxime), a biological method of eradication was developed. This method demonstrated the general advantage of using biological agents. The bacterium *Bacillus thuringiensis* appeared to be very selective in killing only *Simulium* and few other species, and no adaptation of the fly populations was observed. Therefore, the application of a biological agent has the following advantages: (1) it is selective for the target goal; (2) no negative side effects are observed; (3) no rapid adaptation of pests takes place; and (4) the cost of application is lower.

Because of adaptation and other differences, the applicability of basic ecotoxicological principles derived in the temperate region to warm, arid, and cold climates is not without problems [67]. No simple straightforward relation exists for assessing regional differences of toxic effects due to differences in temperature and associated climatic factors. The general belief that metabolic rates are much higher in tropics has not been supported; nevertheless, an increased risk of toxic effects in tropics is to be expected.

3.2.3.3. Impact of Xenobiotics on Pelagic and Benthic Biocenoses

The data bank of the International Register of Potentially Toxic Chemicals (IRPTC) of UNESCO contains a record of some 8000 chemicals, and the number is growing rapidly. Therefore, only a few illustrative examples are described in the following, with an emphasis on related problems. The quantitative aspects of the

Figure 44. Behavior of hydrophobic xenobiotics in standing waters (after [386])

processes and predictions of the impacts of xenobiotics are described in Section 3.3, dealing with ecotoxicological modeling.

An example of the dependence of toxicity not just on one element, but on the ratio of several, can be demonstrated by the case of arsenic. REUTHER [391] found for Swedish lakes that, when added as arsenate, arsenic was readily accumulated in plankton at concentrations close to those found in nature. If the ratio P : As was low, arsenic proved toxic at much lower concentrations.

For the trace metals cadmium, lead, copper, and zinc, the effect of external variables on the amounts present in the environment was specific for each element [392]; especially important for Cd and Pb were sediment- and water-related abiotic variables. For the essential trace metals, the variance expressed by the effect of the common physical variables of the surrounding environment was very low: from 25 % for Zn up to 37 % for Cd and Cu. The quantities of the common xenobiotic cadmium in the aquatic environment can be demonstrated by the example of the river Ruhr in Germany (Fig. 45). A long-term effect of Cd on aquatic biocenoses was measured by using the microcosm method [380]. Figure 46 shows a steady decrease of the number of species in the microcosm with increasing cadmium concentration.

Some detergents greatly affect nature not only because of the amount of phosphates they contain (leading to eutrophication of water bodies), but also because of their toxicity. The detergent FIT was found to be highly toxic to frogs and their larvae [394].

Evidence exists of the sometimes close relation between the occurrence of some xenobiotics and the amounts produced in the respective region. Figure 47 shows how the quantities of PCBs, DDT, mirex, and chlorobenzene accumulated per year in layers of some U.S. lake sediments follow the sales or production rates of the respective years.

A systematic study of 50 chemical compounds demonstrated that their joint toxic effects can be considered simply as additive [395]. The authors proposed a quantitative structure–activity relationship (QSAR) technique for predicting the concentrations of the components of mixtures that would cause 50 % inhibition of the toxic effect by joint action. How far the effect of other compounds can act synergistically is not clear.

Range of cadmium concentrations of different waters in the Ruhr area

	Concentration, μg/L
Groundwater	0.05 – 0.15
Drinking water	0.05 – 0.2
Falling rain at Essen	0.2 – 1.1
Storm water flow from paved areas	1–10
Seepage water from sewage sludge deposits	<1
Seepage water from industrial sludge deposits	5–50

Figure 46. Microcosm analysis of the long-term effect of cadmium on the equilibrium number of species (S_{eq}) in aquatic biocenoses (after [380])

3.2.3.4. Ecological Risk Assessment of Xenobiotics

Ecological risk is a condition in which the normal functions of a population, ecosystem, or entire landscape are threatened by external forces or stress factors that, at present or in the future, may diminish the health, productivity, genetic structure, economic value, or aesthetic quality of the system [395]. In addition to xenobiotics, ecological risk may be caused by excessive inputs of nutrients; disturbance of normal energy flow by thermal pollution or global warming due to greenhouse gases; drastic changes in ecosystem structure from drying peatlands; and physical destruction of ecosystems by excessive grazing of rangelands, burning of forests, or covering with heavy loads of industrial dust.

Ecosystem risk assessment is defined as a set of procedures for measuring risk to the environment associated with the use of xenobiotics through an objective and probabilistic exercise based on empirical data and scientific judgment. The results of such a risk assessment can then be used to provide a consistent means of estimating the limiting concentrations of substances that will produce no unacceptable negative effects on ecosystems that may be exposed to the substance (see Section 3.2.5). The phases of making and reviewing an environmental risk assessment are presented in Figure 48. More about the method can be found in [68], [397], [398].

Concluding Remarks. The consequences of massive application of xenobiotics in Vietnam are drastic. Pesticide damage to nature involved the death of millions of trees and often their ultimate replacement by grasses, maintained in turn by subsequent periodic fires; deep and lasting inroads into the mangrove habitat; widespread site debilitation via soil erosion and loss of nutrients in solution; decimation of terrestrial wildlife, primarily through destruction of their habitat; losses in freshwater fish, largely because of reduced availability of food species; and a possible contribution to the decline of offshore fishery. Humans are suffering both direct and indirect effects. In addition to a variety of health problems of exposed humans, the abovementioned widespread damage to the inland and coastal forest ecosystems has had major indirect effects due to large-scale devastation of crops [67].

In the future, additional complications must be expected in the framework of xenobiotic application. These will be connected not only with the continuing adaptation of target organisms but also with changes in the total environment that are expected to be global. These include global warming accompanied by shifts in species composition, in food crops and production, and in conditions for human life. A mistake has been made in conceding to chemicals the right to be judged innocent until proven guilty. Therefore, a new strategy toward the application of xenobiotics is necessary, based on the following rules:

1) Minimize the number of newly invented chemicals in production and commercial use
2) Minimize the number of chemicals used in social and economic activities
3) Give priority to naturally occurring rather than synthetic chemicals
4) Give priority to the production of solid substances over liquids and liquids over gases
5) Minimize the spatial scope and time of their presence in the environment

3.2.4. Testing Approaches to Atmospheric Effects

Biotic Effects. For atmospheric hazard assessment, biotic and abiotic approaches are

Figure 47. Annual accumulation rates of PCBs, DDT, mirex, and chlorobenzene in sediments of selected U.S. lakes (after [386])
E-30 and G-32 represent two different sampling stations (cores)

possible, although internationally accepted test guidelines to more precisely define the effects of airborne contaminants on organisms have not yet been developed. In most cases, only data on acute mammalian toxicity are available, which can be used for rough estimation of the risk a chemical poses for animals. However, atmospheric concentrations are normally not high enough to cause acute toxic effects. Therefore, data on long-term or chronic toxicity or on mutagenic and teratogenic effects would be more appropriate (→ Air, Chap. 3.).

Concerning the toxicity to terrestrial plants [2], no standardized test procedures are available for chemicals applied directly in gaseous or deposited form since a guideline for tests with herbaceous species has not yet been accepted. For some chemicals, enquiries into invertebrate toxicity – mostly insects (e.g., *Apis mellifera, Syrphus corollae*) – are available, which were conducted according to guidelines for the testing of plant protection agents.

Abiotic Effects. As regards abiotic effects, consideration of the following atmospheric

Figure 48. Environmental risk assessment (after [396])

processes is indicated [399]: global warming, stratospheric ozone depletion, tropospheric ozone formation, and acidification. A potential greenhouse gas has absorption bands in the 800–1200-cm^{-1} atmospheric window. Its *global warming potential* (GWP) is defined as the ratioof calculated warming for each mass unit of a gas emitted into the atmosphere relative to the calculated warming for a mass unit of the reference gas CFC 11 (CCl_3F). An approximate GWP value of a chemical S is given by

$$GWP = \frac{\tau_s M_{CFC11} S_s}{\tau_{CFC11} M_s S_{CFC11}} \tag{77}$$

where τ_s is the atmospheric lifetime ($\tau_{CFC11} = 60$ a); M_s the molar mass ($M_{CFC11} = 137$ g/mol); and S_s the IR absorption strength in the interval $800-1200\,cm^{-1}$ ($S_{CFC11} = 2389\,cm^{-2}$ bar).

In the above formula, the atmospheric lifetime is defined as

$$\tau = \frac{1}{k_d + k_w + k_c} \tag{78}$$

where k_d is the removal rate for dry deposition; k_w the removal rate for wet deposition; and k_c the pseudo-first-order chemical transformation rate.

A substance may have an impact on *stratospheric ozone* when its atmospheric lifetime is sufficiently long to allow for transport to the stratosphere and it contains chlorine or bromine substituents [290]. The ozone-depletion potential (ODP) is then defined as the ratio of calculated ozone change for a unit mass of gas emitted into the atmosphere relative to the depletion determined for an equal mass of the reference gas CFC 11 (ODP = 1). Thus, the ODP value can be approximated by

$$\mathrm{ODP} = \frac{\tau_s M_{\mathrm{CFC11}} n_{\mathrm{Cl}} + \alpha n_{\mathrm{Br}}}{\tau_{\mathrm{CFC11}} M_s 3} \quad (79)$$

where τ_s is the atmospheric lifetime ($\tau_{\mathrm{CFC11}} = 60$ a); M_s the molar mass of gas considered ($M_{\mathrm{CFC11}} = 137$ g/mol); $n_{\mathrm{Cl}}, n_{\mathrm{Br}}$ the numbers of Cl and Br atoms, respectively, per molecule; and α a measure of the effectiveness of Br in ozone depletion with respect to Cl ($\alpha = 30$).

The generation of *tropospheric ozone* depends on

1) The reactivity of the substance and the degradation pathway
2) The meteorological situation, with highest O_3 concentrations expected at high temperatures, intense solar radiation, and low wind speeds
3) The concentration of air pollutants, where the concentration of nitrogen oxides has to exceed several $\mu L/m^3$

Less reactive species (eg., CH_4 or CO) are important for long-term O_3 concentrations, while highly reactive species such as alkylenes or aldehydes contribute significantly to ozone peaks.

In analogy to the above depletion potential a photochemical ozone formation potential (POCP index) has been defined, based on ethylene, which has a POCP value of 100. Comparative studies showed, however, considerable variability in the POCP values assigned to each organic compound, which is difficult to explain by recourse to the basic chemical characteristics alone [2]. Therefore, ozone formation is best derived from an approximate reactivity scale based on the rate constant for the (hydrocarbon + OH·) reaction and molar mass [290]:

$$\mathrm{OH}^{\cdot}\, scale = \frac{k_s M_{\mathrm{ethylene}}}{M_s k_{\mathrm{ethylene}}} \cdot 100 \quad (80)$$

where k_s is the rate constant at $T = 298$ K for the reaction with OH radicals ($k_{\mathrm{ethylene}} = 8.5 \times 10^{-12}\ \mathrm{cm^3\ mol^{-1}\ s^{-1}}$) and M_s is the molar mass ($M_{\mathrm{ethylene}} = 28$ g/mol). For a presentation of pollutant impact on metals, organic and inorganic nonmetallic materials, see [2].

3.2.5. Appraisal

Hazard assessment of chemicals is based on stepwise determinations of predicted environmental concentrations and ecotoxicological no-effect concentrations followed by comparison of the two values. Figures 49 and 50 [239] indicate that whenever the PEC/PNEC ratio is <1.0, the chemical may be concluded not to present an environmental hazard under the conditions analyzed.

In addition to and as a substitute for specifically designed networks yielding spatially representative data, fate and exposure models are useful tools for estimating concentrations and are increasingly applied in many situations. In view of the considerable number of models available, careful selection is indicated to comply with specific problems. The fundamental problem is to define the set of questions a model is expected to answer and accuracy required at a given scale. Even if a suitable model has been chosen and valid input data have been obtained, the results can still be misinterpreted if the underlying principles are not understood properly. Thus, both the assumptions and the limitations of different modeling approaches must be recognized (see Section 3.3).

The first field of model application is the assessment of the fate of chemicals at a specific location (i.e., predicting concentrations related to well-defined sources of emission). The second is the screening of chemicals whose purpose is the evaluation of potential exposure, typically at larger or even global scales. Therefore, consideration of an average environment appears justified in the latter case.

As in the case of monitoring networks [2], the networks providing input data for the calibration and validation of models also require a geostatistical control to allow for interpolation and spatial extrapolation. Only in the case of site-specific modeling is strict validation possible, while for screening models proper validation cannot be ensured, because no specific situation is available as a reference [238]. Validation of probabilistic models is possible, but this requires a substantial amount of valid environmental concentration measurements in different locations to allow geostatistical analysis of the primary data.

As summarized in Figure 49, the principle of effects assessment is to use toxicity data from

Figure 49. Exposure assessment scheme (after [239])

Figure 50. Effects assessment scheme (after [239])

short- and long-term experiments and appropriate assessment factors to calculate a PNEC value. In principle, this is accomplished separately for each environmental compartment, but practical difficulties may arise from the fact that most of the ecotoxicity data on existing chemicals were obtained for the aquatic compartment only.

Aquatic Hazard Assessment. According to the base set definition [289], [290], acute effect data for fish, *Daphnia*, and algae should be available. In addition, chronic toxicity investigations with standard or nonstandard organisms (see Section 3.2.1.3) may also be available. Multispecies tests, micro- and mesocosm studies, and field tests are comparatively rare for most chemicals [296]. The standard organisms used represent three trophic levels – primary producers and primary and secondary consumers – but in view of the great variability of aquatic phyto- and zoocenoses, their functional representativeness should be evaluated more precisely. In addition, a given population may represent more than one trophic level depending on the amount and spectrum of nutrition for the species; earlier life stages not infrequently live on completely different food than adults of the same species.

Therefore, ecotoxicological data collected in laboratory experiments can be difficult to translate into accurate predictions of effects in ecosystems. This applies in particular if the duration of a test is different from that of standard tests or if the test parameters (e.g., end points) are not comparable to those used in standardized test procedures (e.g., investigations of photosynthesis or behavior, studies conducted on the cellular or subcellular level).

In general, the use of laboratory test data will lead to an overestimate of chemicals' effects on complex aquatic ecosystems, which implies very conservative assessment factors, for the following reasons:

1) Bioavailability of chemicals is maximized in filtered-water laboratory systems, while in natural waters the higher concentrations of dissolved organic matter and suspended solids may reduce it substantially as a result of adsorption or complexation [291].
2) In laboratory tests, exposure concentrations are kept constant as far as possible, whereas in natural waters, exposure is likely to vary over time and degradation is greater. An overestimate is obvious when relatively long-term laboratory toxicity studies are the basis for extrapolation.
3) Laboratory experiments are normally conducted with a limited number of individuals or monospecific communites (e.g., *Daphnia magna*) and therefore exclude the various homoeotic mechanisms operating in complex natural multispecies communities.

The following features of laboratory experiments are likely to lead to an underestimate of toxic effects in ecosystems:

1) Few test species are used in laboratory test systems (see Section 3.2.1.3); therefore, they cannot be expected to encompass the most susceptible species in the field. In addition, the definition of sensitivity is dependent largely on the choice of the respective end point.
2) Information on the toxicity of substances normally relates to individual substances, while in nature complex mixtures are often present. Their effects may be additive, but the extent to which toxicant concentrations lower than the NOEC can contribute to toxicity is not yet clear [400–402].
3) In the laboratory, efforts are normally made to remove stressors other than the substance tested. In the field, however, a variety of stressors (e.g., temperature, drought, or disease) may contribute to increase the susceptibility to a chemical well above that found in the laboratory.
4) The use of fixed assessment factors between acute EC_{50} values and chronic NOECs excludes the possibility that differences in toxic mechanisms exist between acute and chronic exposure.
5) The same applies to fixed assessment factors between chronic NOECs and ecosystem NOECs since the history of the ecosystem in a monitoring study is not always known precisely enough. Therefore, an observed "anomaly" in ecosystem behavior cannot be conclusively attributed to the presence of a substance at the time of monitoring.

Hazard Assessment for Sediments. In comparison to aquatic hazard assessment, anal-

ogous approaches for sediments have not yet reached the same level of standardization. Various techniques (e.g., equilibrium partitioning, determination of interstitial water quality, or spiked sediment toxicity) are under discussion [292]. As long as ecotoxicological effect data on sediment-dwelling organisms are lacking, the $\mathrm{PNEC_{sed}}$ may be approximated by the PNEC for aquatic taxa and the sediment – water partitioning coefficient K according to the following formula:

$$PNEC_{sed} = K \cdot \mathrm{PNEC_{water}} \tag{81}$$

Terrestrial Hazard Assessment. Hitherto, hazard assessment schemes have been based predominantly on data obtained on aquatic organisms, while the amount of valid data on sediment and soil organisms, particularly of data obtained under realistic exposure conditions, is distinctly lower. Therefore, data obtained for aquatic test organisms should be used as an inital approach only to indicate whether terrestrial tests must be performed.

Aquatic organisms might display a similar susceptibility to chemicals compared to soil organisms exposed mainly to the pore water of the soil, but the transferability of aquatic effect values to pore water organisms requires further examination on the basis of comparative tests with chemicals of various groups. These have to make proper allowance for the fact that most chemicals relevant for soil either are resistant to degradation, show a strong adsorption to soil, or have a certain bioaccumulation potential. However, even readily biodegradable chemicals such as detergents may pose a problem for the terrestrial environment if applied in considerable amounts. Therefore, in many cases an adsorption potential may be more a supposition of biodegradibility than an exclusion criterion.

If no acute tests are available, one test with higher plants and one test with earthworms or microorganisms merit particular attention since they are involved in the transformation of organic matter and contribute considerably to the transformation potential of a terrestrial ecosystem.

Extrapolation of test results obtained for vertebrates (i.e., mice, rats, or birds) on the effects of a chemical in the field is difficult because of behavior- or stress-related individual or specific responses of the test organisms [255]. Furthermore, the assessment of critical environmental concentrations must be based on concentration estimates in the soil, which lead to effects via ingestion [403].

Fuzzy Set and Fuzzy Logic Applications in Ecological Research. A fuzzy set and a fuzzy logic approach [404] can be used to solve some problems of uncertainty in ecotoxicological research and practice, namely, the uncertainty of data and uncertainty of expert knowledge. Compared with the conventional methods of information processing, the application of the fuzzy set theory offers a better applicability of imprecise data and vague knowledge. This involves

1) The representation and processing of imprecise data in the form of fuzzy sets
2) The representation and processing of vague knowledge in the form of linguistic rules with imprecise terms defined as fuzzy sets

Two main applications of the fuzzy set theory in ecological and ecotoxicological research are data analysis and knowledge-based modeling. Conventional clustering methods definitely placed an object within only one cluster. With *fuzzy clustering*, an object need not be definitely placed within one cluster since the membership value of this object can be split up between different clusters. In comparison to conventional clustering methods, distribution of the membership value thus provides additional information from which the membership value can be interpreted as the degree of similarity between properties of a particular object and properties represented by particular clusters.

Kriging belongs to the most popular methods of spatial interpolation of data, but its application is sometimes restricted owing to an insufficient amount of data. The amount of available measurement data is often too low for conventional kriging methods, or exact data may be unavailable at some locations in the study area. In such a case, the data set can be completed by using additional imprecise data estimated subjectively by an expert. *Fuzzy kriging* is a modification of the conventional kriging procedure that utilizes exact (crisp) measurement data as

well as imprecise estimates obtained from an expert. These imprecise data are defined as so-called fuzzy numbers (a fuzzy number is a fuzzy set whose membership function is convex and takes its maximal value 1 for only one parameter value). Fuzzy kriging can be used to estimate interpolated values in the form of fuzzy numbers reflecting the imprecision of the input data.

Fuzzy knowledge-based modeling can be particularly useful when no analytical model of the relations to be examined exists or data are insufficient for statistical analysis [405]. To facilitate the construction of fuzzy knowledge-based models of complex ecological or toxicological systems, a modeling support system based on fuzzy logic (FLECO) has been developed [406–408]. The FLECO procedure employs fuzzy logic to handle inexact reasoning and fuzzy sets to handle the uncertainty of data. The main tasks of this system are

1) To facilitate the creation of the fuzzy knowledge base
2) To simplify changes within the fuzzy knowledge base
3) To create and facilitate the connections between submodels
4) To offer a set of inference methods
5) To facilitate the simulation process

3.3. State of the Art of Modeling in Ecotoxicology

3.3.1. Characteristics of Ecotoxicological Models

An increasing interest in management of pollution by toxic substances has emerged during the 1980s, and this has caused an equally large interest in toxic substance modeling. Models for toxic substances attempt to model the fate and effect of these substances in ecosystems. These models are management models, deterministic models, more frequently compartment models than matrix models, holistic models, and lumped models (because the difficulty of determining parameters is greater than for ecological modeling in general). Toxic substance models are most often biogeochemical models because they attempt to describe the mass flows of the toxic substances considered, although models of population dynamics also exist, which include the influence of toxic substances on birthrate or mortality and therefore should be considered toxic substance models.

Toxic substance models differ from other ecological models by the following:

1) The need for parameters to cover all possible toxic substance models is great, and general estimation methods are therefore used widely. Section 3.3.5 is devoted to this question.
2) The safety margin should be high when, for instance, expressed as the ratio between the actual concentration and the concentration that produces undesired effects.
3) The possible inclusion of an effect component, which relates the output concentration of a toxic substance to its effect, is easy. However, finding a well-examined relationship to base it on is often a problem.
4) The need is for simple models because of items (1) and (2), and because of limited knowledge of process details, parameters, sublethal effects, antagonistic and synergistic effects.

Several questions must be clarified before a toxic substance model can be developed in accordance with the general procedure used for development of ecological models. The following information must be available:

1) The best possible knowledge about the processes in which the toxic substance considered is involved in the ecosystem (as far as possible, knowledge about the quantitative importance of the processes should be obtained)
2) Obtaining parameters from the literature and/or from experiments (in situ or in the laboratory)
3) Estimation of all parameters by the methods presented in Section 3.3.5
4) Comparison of the results from items (2) and (3) and an attempt to explain the discrepancies
5) Estimation of which processes and state variables should be included in the model (if the slightest doubt exists at this early stage, too many processes and state variables should be included rather than too few)

6) Use of sensitivity analysis to evaluate the significance of individual processes and state variables, which in many cases will lead to further simplification

Section 3.3.2 reviews the characteristic features of ecotoxicological models and tries to classify them. Section 3.3.3 gives an overview of some of the ecotoxicological models published during the last 10 – 15 years. The description of the chemical, physical, and biological processes in the models will, in general, be in accordance with equations generally applied for physicochemical and biological processes. Some submodels of particular ecotoxicological interest are presented in Section 3.3.4. Section 3.3.5 deals with parameter estimation methods, which are of particular importance in ecotoxicological models. Section 3.3.6 is devoted to fugacity models in general, including their basic equations, and a case study in which the fugacity modeling approach is used is presented.

3.3.2. Classification of Ecotoxicological Models

Ecotoxicological models differ from ecological models in general by

1) Most often being more simple
2) More parameters are unknown, cannot be found in the literature
3) Wider use of parameter estimation methods
4) Possible inclusion of an effect component

Ecotoxicological models can be divided into six classes. The classification presented here is based on differences in the modeling structure. The decision on which model class to apply will be based on the ecotoxicological problem to be solved. The definitions of model classes are given below, along with the most appropriate use of each model type.

Class 1. Food Chain or Food Web Dynamic Models. Class 1 models consider the flow of toxic substances through the food chain or food web. Such models are relatively complex and contain many state variables. The models furthermore contain many parameters, which often have to be estimated by one of the methods presented in Section 3.3.5. These types of model are used when a great number of organisms are affected by the toxic substance, or the entire structure of the ecosystem is threatened by the presence of a toxic substance. Because of their complexity, these models have not been used widely. They are similar in many aspects to the more complex eutrophication models that consider the flow of nutrients through the food chain or even through the food web. In some instances, they are even constructed as submodels of a eutrophication model (see, for instance, [409]). Figure 51 shows a conceptual diagram of an ecotoxicological food chain model for lead. Lead from atmospheric fallout and wastewater enters an aquatic ecosystem, where it is concentrated through the food chain. Simplification is rarely possible for this model because the aim of the model is to describe and quantify the bioaccumulation and ecological magnification through the food chain.

Figure 51. Conceptual diagram of lead accumulation in the food chain of an aquatic ecosystem

Class 2. Static Models of the Mass Flow of Toxic Substances. If seasonal changes are minor, or of minor importance, a static model of the mass flows is often sufficient to describe the

situation and even indicate the expected changes if the input of toxic substances is reduced or enlarged. This type of model is based on a mass balance as shown in the example in Figure 52. It often, but not necessarily, contains more trophic levels, and the modeler often is concerned with the flow of the toxic substance through the food chain. If some seasonal changes occur, this type, which in most cases is simpler than class 1, can still be used advantageously, for instance, if the modeler is concerned with the worst case of seasonal changes.

Class 3. Dynamic Model of a Toxic Substance in a Trophic Level. Often only the toxic substance concentration in one trophic level is of concern. This includes the zero trophic level, which is understood as the medium soil, water, or air. Figure 53 shows a model of copper contamination in an aquatic ecosystem as an example. The main concern is the copper concentration in the water, which may reach a toxic level for phytoplankton. Zooplankton and fish are much less sensitive to copper contamination, so the "alarm clock" rings first at the concentration level that is harmful to phytoplankton. However, only dissolved copper ions are toxic, and therefore the partition of copper in ionic, complex-bound, and adsorbed forms must be modeled. The exchange between copper in the water phase and in sediment is also included because sediment can accumulate relatively large amounts of heavy metals. The amount released from sediment may be significant under certain circumstances, for instance, at low pH.

Figure 54 gives another example. Here, the main concern is the DDT concentration in fish, which may be so high that, in accordance with WHO standards, the fish are unfit for human consumption. The model can therefore be simplified by including not the entire food chain but only fish. Some physicochemical reactions in the water phase are, however, important and are included in the diagram.

The so-called HESP model [260] estimates exposure, or the total concentration of a toxic substance for individuals living at a contaminated site. A number of possible exposure routes are identified and subsequently quantified in the model. The model can be used to initiate a hazard assessment process, which can provide a sound basis for decisions regarding possible measures.

As seen from these examples, simplifications are often feasible when the problem is well defined. Simplifications take into account which component is most sensitive to toxic matter and which processes are most important for concentration changes.

Class 4. Ecotoxicological Models in Population Dynamics. Population models are biodemographic models and therefore have numbers of individuals or species as state variables. The simple population models consider only one population. Population growth is the difference between natality and mortality:

$$dN/\mathrm{d}t = B \cdot N - M \cdot N = r \cdot N \tag{82}$$

where N is the number of individuals; B is the natality (i.e., the number of new individuals per unit of time and unit of population); M is the mortality (i.e., the number of organisms that died per unit of time and unit of population); and r is the increase in number of organisms per unit of time and unit of population (i.e., $B - M$). The concentration of a toxic substance in the environment or in the organisms influences natality and mortality, and if the relations between the concentration of a toxic substance and these population dynamic parameters are included in the model, it becomes an ecotoxicological model of population dynamics.

Population dynamic models may include two or more trophic levels, and ecotoxicological models will include the influence of the concentration of the toxic substance on natality, mortality, and interactions between these populations. In other words, an ecotoxicological model of population dynamics is a general model of population dynamics with the inclusion of the relation between toxic substance concentrations and some of the model parameters.

Class 5. Ecotoxicological Models with Effect Components. Although class 4 models include relations between concentrations of toxic substances and their effects, these are limited to population dynamic parameters. In comparison, class 5 models include more comprehensive relations between concentrations of toxic substances and effects. These models may include not only lethal or sublethal effects but also effects on biochemical reactions or on the enzyme

Figure 52. Static model of the daily lead uptake of an average Dane

Figure 53. Conceptual diagram of a simple copper partition model

Figure 54. Conceptual diagram of a simple DDT partition model

system. As Figure 55 shows, the effects on various levels of the biological hierarchy may be considered from cells to ecosystems.

Figure 55. Conceptual diagram of ecotoxicological models with effect components on various levels of biological complexity

In many problems, more details about the effects may be required to answer the following relevant questions:

1) Does the toxic substance accumulate in the organism?
2) What will the long-term concentration in the organism be when uptake rate, excretion rate, and biochemical decomposition rate are considered?
3) What is the chronic effect of this concentration?
4) Does the toxic substance accumulate in one or more organs?
5) What is the transfer between various parts of the organism?
6) Will decomposition products eventually cause additional effects?

A detailed answer to all of these questions may require a model of the processes that take place in the organism and a translation of concentrations in various parts of the organism into effects. This implies, of course, that the intake = (uptake by the organism) × (efficiency of uptake) is known. Intake may be from either water or air, which can also be expressed by the use of concentration factors (the ratios between the concentration in the organism and that in air or water).

However, if all of the aforementioned processes are considered for just a few organisms, the model will become too complex, contain too many parameters to calibrate, and require more detailed knowledge than can be provided. Therefore, most models in this class do not consider too many details of the partition of toxic substances in organisms and their corresponding effects, but rather are limited to simple accumulation in the organisms and their effects. In most cases, accumulation is rather easy to model, and the following simple equation is often sufficiently accurate:

$$dC/\mathrm{d}t = (e_\mathrm{f} \cdot C_\mathrm{f} \cdot F + e_\mathrm{m} \cdot C_\mathrm{m} \cdot V)/W - Ex \cdot C = (INT)/W - Ex \cdot C \quad (83)$$

where C is the concentration of the toxic substance in the organism; e_f and e_m are the efficiencies for the uptake from the food and medium, respectively (water or air); C_f and C_m are the concentration of the toxic substance in the food and medium, respectively; F is the amount of food uptake per day; V is the volume of water or air taken up per day; W is the body weight as either dry or wet matter; and Ex is the excretion coefficient (d^{-1}). As seen from the equation, INT covers the total intake of toxic substance per day.

This equation has a numerical solution:

$$C/C\,(\max) = \{INT \cdot [1 - \exp(Ex \cdot t)]\}/(W \cdot Ex) \quad (84)$$

where C (max) is the steady-state value of C:

$$C\,(\max) = INT/(W \cdot Ex) \quad (85)$$

i.e., the concentration of the toxic substance approximates a steady-state value after a certain time interval.

Class 6. Fate Models with or without a Risk Assessment Component. The last type of ecotoxicological models focuses on the fate of toxic substances: Where in the ecosystem will the toxic substance be found? In what concentration? These models are sometimes called multimedia models because they focus on the distribution of toxic substances in the four spheres. The complete solution of an ecotoxicological problem requires in principle four (sub)models, of which the fate model may be considered the first model in the chain; see Figure 56. The four components are [410] (1) a fate or exposure model; (2) an effect model, translating the concentration into an effect (see class 5); (3) a model for human perception processes; and (4) a model for human evaluation processes. The first two submodels are in principle "objective," predictive models, whereas the latter two are value oriented. The development of submodels (1) and (2) is based on physical, chemical, and biological processes. They are very similar to other environmental models and are based on mass transfer; mass balances; and physical, chemical, and biological processes.

The second submodel requires good knowledge of the effects of the toxic components. Submodels (3) and (4) differ from the generally applied environmental management models and are presented in some details below in the discussion of risk assessment.

Fugacity models (see Section 3.3.6) are a special type of fate model. They attempt to answer the following questions: In which of these six compartments (air, water, soil, sediment, suspended sediment, and biota) can the greatest problem be expected for chemicals emitted to the environment? What concentration will be expected in each compartment? What are the implications of these concentrations? The fugacity models are to a large extent based on physicochemical parameters and the use of these parameters to estimate other required parameters. The applicability of the fugacity model is therefore very dependent on the use of the estimation methods presented in Section 3.3.5.

The risk assessment component, associated with the fate model comprises human perception and evaluation processes (see Fig. 56). These submodels are explicitly value laden but must of course build on objective information about concentrations and effects. Factors that may be important to consider in this context are

1) Magnitude and time constant of exposure
2) Spatial and temporal distributions of concentrations
3) Environmental conditions determining the process rates and effects
4) Translation of concentrations into magnitude and duration of effects
5) Spatial and temporal distribution of effects
6) Reversibility of effects

The uncertainties relating to the information on which the model is based and the uncertainties related to the development of the model, are crucial in risk assessment. The uncertainty in risk assessment may be classified in one or more of the following five categories:

1) Good direct knowledge and statistical evidence on the important components (state variables, processes, and interrelations of the variables) of the model are available.
2) Good knowledge and statistical evidence on the important submodels are available, but the aggregations of the submodels are less certain.
3) No good knowledge of the model components for the considered system is available, but good data are available for the same processes from a similar system, and these data are considered applicable for use directly or with minor modifications, to the model development.
4) Some, but insufficient, knowledge ist available from other systems. Attempts are made to use these data without the necessary transferability. Attempts are made to eliminate gaps in knowledge by the use of additional experimental data as far as possible within the limited resources available for the project.
5) The model is to a large extent based on the subjective judgment of experts.

Acknowledgment of the uncertainty is of great importance and may be taken into consideration, either qualitatively or quantitatively. Another problem is of course: Where and how should the uncertainty be taken into account? Should the economy or the environment benefit from the uncertainty? If the results of the management strategy are to be ensured, the un-

Figure 56. Components and general structure of comprehensive ecotoxicological modeling systems

certainty must be used to reduce the emission standards.

Until 10 – 15 years ago, researchers had very little understanding of the processes by which people actually perceive the exposures and effects of toxic chemicals, but these processes are just as important for risk assessment as the exposure and effect processes. The following list of risk characteristics summarizes the concerns:

1) Is the risk voluntary or involuntary?
2) Are the levels known to the exposed people or only to science?
3) Is the risk novel, or old and familiar?
4) Is it common or dreaded (e.g., does it involve cancer) ?
5) Does it involve death?
6) Are mishaps controllable?
7) Are future generations threatened?
8) Is the risk global, regional, or local?
9) Is the risk a function of time? How does it depend on time (e.g., increase or decrease) ?
10) Can it be reduced easily?
11) Is the expected effect immediate or delayed?
12) Are many or a few people involved?
13) Are the effects observable immediately?

A factor analysis has been performed by Slovic et al. [411] that shows, among other results, a not surprising emphasis on people's perception of dreadful and unknown risks. Broadly speaking, two methods of selecting the risks exist. The first may be described as the *rational actor model*, involving people that look systematically at all the risks they face and make choices about which they will live with and at what levels. For decision making, this approach would use some single, consistent, objective functions and a set of decision rules. The second method may be called the *political – cultural model*. It involves interactions among culture, social institutions, and political processes for the identification of risks and the determination of those that people will live with and at what level.

Both methods are unrealistic, since they are both completely impractical in their pure form. Therefore, a strategy for risk abatement must be selected that is founded on a workable alternative based on the philosophy behind both methods.

Several risk management systems are available. Here, some recommendations should be given for the development of risk management systems:

1) Consider as many of the characteristics listed above as possible and include human perception of these characteristics in the model.
2) Do not focus too narrowly on certain types of risks; this may lead to suboptimal solutions. Attempt to approach the problem as broadmindedly as possible.
3) Choose strategies that are pluralistic and adaptive.
4) Benefit – cost analysis is an important element of the risk management model, but it is far from being the only important element, and the uncertainty in evaluation of benefit

and cost should not be forgotten. The variant of this analysis applicable to environmental risk management may be formulated as follows :
Net social benefit = social benefits of the project minus "environmental" costs of the project

5) Use multiattribute utility functions, but remember that people in general have trouble thinking about more than two to three (at most, four) attributes in each outcome.

Presentation of the six classes of models above clearly shows the advantages and limitations of ecotoxicological models. The simplifications used in classes 2, 3, and 6 (at least without risk assessment components) often offer great advantages. They are sufficiently accurate to give a very applicable picture (overview) of the concentrations of toxic substances in the environment, because of the use of large safety factors. Application of the estimation methods presented in Section 3.3.5 makes feasible the construction of such models, even though knowledge of the parameters is limited. The estimation methods obviously have a high uncertainty, but the great safety factor helps in accepting this uncertainty. On the other hand, knowledge about the effects of toxic substances is very limited, particularly at the organism and organ level. Therefore, models with effect components must not be expected to give more than a first rough picture of what is known today in this area.

Because of the character of ecotoxicological models, a few questions should be clarified before beginning the modeling procedure:

1) Obtain the best possible knowledge about the processes of the toxic substance under consideration
2) Attempt to get parameters of the processes in which the toxic substance is involved in the environment from the literature
3) Estimate all parameters using methods presented in Sections 3.3.4 and 3.3.5
4) Compare the results from items (2) and (3) and attempt to explain discrepancies, if present
5) Use sensitivity analysis widely to estimate which processes and state variables would be feasible and relevant to include in the model

3.3.3. An Overview: Application of Models in Ecotoxicology

Some toxic substance models are reviewed in Table 20 to give an idea of the types of models available today. Most models reflect the proposition that good knowledge of the problem and the ecosystem can be used to make reasonable simplifications. Model characteristics indicated in Table 20 are state variables or processes considered in the model. Note the number of modeled toxic substances and the processes taken into account. The model class, according to the classification 1 to 6 discussed in Section 3.3.2, is given in brackets after the toxic substance. Only a few class 4 models are included in Table 20. Ecological modeling has been approached from two sides: population dynamics and biogeochemical flow analysis. Since the second approach has been most involved in environmental issues, the toxic substance problem has also been approached from this angle. The few class 4 models, including the example given in Table 20, are population dynamic models, with some additional equations to account for the influence of toxic substances on natality and mortality. Provided these relations are available, constructing this type of model should be relatively easy.

The most difficult part of modeling the effect and distribution of toxic substances is obtaining relevant knowledge about the behavior of toxic substances in the environment and using this knowledge to make feasible simplifications. The modeler of ecotoxicological problems is particularly challenged to select the proper, balanced complexity, and many examples can be found of rather simple ecotoxicological models that are able to solve the basic problem.

It can be seen from the overview in Table 20 that most ecotoxicological models have been developed during the last decade. Before ca. 1975, toxic substances were rarely associated with environmental modeling, since the problems seemed straightforward. The many pollution problems associated with toxic substances were believed to be easily solved simply by eliminating the source of the toxic substance. During the 1970s, the environmental problems originating from toxic substances were acknowledged to be very complex because of the interaction of

Table 20. Examples of toxic substance models

Toxic substance, model class	Model characteristics	Reference
Cadmium (1)	food chain similar to a eutrophication model	[412]
Mercury (6)	6 state variables: water, sediment, suspended matter, invertebrates, plant, fish	[413]
Vinyl chloride (3)	chemical processes in water	[414]
Methyl parathion (1)	chemical processes in water and microbial degradation and adsorption of benzothiophene, 2 – 4 trophic levels	[415]
Methyl mercury (4)	a single trophic level: food intake, excretion, metabolism, growth	[416]
Heavy metals (3)	concentration factor, excretion, bioaccumulation	[417]
Pesticides in fish, DDT and methoxychlor (5)	ingestion, concentration factor, adsorption on body, defecation, excretion, chemical decomposition, natural mortality	[418]
Zinc in algae (3)	concentration factor, secretion, hydrodynamic distribution	[419]
Copper in the sea (5)	complex formation, adsorption, sublethal effect of ionic copper	[420]
Lead (5)	hydrodynamics, precipitation, toxic effects of free ionic lead on algae, invertebrates, and fish	[421]
Radionuclides (3)	hydrodynamics, decay, uptake, and release by various aquatic surfaces	[69]
Radionuclides (2)	in grass, grains, vegetables, milk, eggs, beef, and poultry–state variables	[422]
SO_2, NO_x, and heavy metals on spruce forests (5)	threshold model for accumulation effect of pollutants (air and soil)	[369]
Toxic environmental chemicals in general tests (6)	hazard ranking and assessment from physicochemical and a limited number of laboratory data	[423]
Heavy metals (3)	adsorption, chemical reactions, ion exchange	[424]
Polycyclic aromatic hydrocarbons (3)	transport, degradation, bioaccumulation	[424]
Persistent toxic organic substances (3)	groundwater movement, transport and accumulation of pollutants in groundwater	[425]
Cadmium, PCB (2)	hydraulic overflow rate (settling), sediment interactions, steady-state food chain submodel	[409]
Hydrophobic organics (3)	gas exchange, sorption/desorption, hydrolysis compounds, photolysis, hydrodynamics	[426]
Mirex (3)	water – sediment exchange processes, adsorption, volatilization, bioaccumulation	[427]
Toxins (aromatic hydrocarbons, Cd) (3)	hydrodynamics, deposition, resuspension, volatilization, photooxidation, decomposition, adsorption, complex formation, (humic acid)	[428]
Heavy metals (2)	hydraulic submodel, adsorption	[429]
Oil slicks (3)	transport and spreading, influence of surface tension, gravity, and weathering processes	[430]
Acid rain (soil) (3)	aerodynamics, deposition	[70]
Acid rain	C, N, and S cycles and their influence on acidity	[431]
Persistent organic chemicals (6)	fate, exposure, and human uptake	[432]
Chemicals, general (6)	fate, exposure, ecotoxicity for surface water and soil	[433]
Toxicants, general (4)	effect on populations of toxicants	[434]
Chemical hazard (6)	basin-wide ecological fate	[435]
Pesticides (4)	effects on insect populations	[436]
Insecticides (2)	resistance	[437]
Mirex and lindane (6)	fate in Lake Ontario	[427]
Pesticides (3)	degradation in soil	[438]
Pesticides (3)	degradation in soil	[439]
Pesticides (3)	leaching to groundwater	[440]
Acid rain (5)	effects on forest soils	[70]
Acid rain (5)	cation depletion of soil	[441]
pH, calcium, and aluminum (4)	survival of fish populations	[442]
Photochemical smog and NO_x (6)	fate and risk	[443]
Nitrate (3)	leaching to groundwater	[444]
Oil spill (6)	fate	[445]
Toxicants (4)	effects on populations	[446]
Chromium (2)	distribution and accumulation in mussels	[71]
Toluene, benzene, Zn, Ni, Pb (3)	assess exposure levels of soil contaminants for humans	[447]

many sources and of many processes and components simultaneously. Several accidental releases of toxic substances into the environment have reinforced the need for models. Thus, various ecotoxicological models have been developed since the late 1970s. The list in Table 20 represents a comprehensive survey of available ecotoxicological models, but it should not be considered complete since it is not the result of an exhaustive literature review.

Table 21. Regression equations for estimation of concentration, bioconcentration, and ecological magnification factors

Indicator	Relationship	Correlation coefficient	Range (indicator)
K_{ow}	$\log CF = -0.973 + 0.767 \log K_{ow}$	.76	$2.0\times10^{-2} - 2.0\times10^{6}$
K_{ow}	$\log CF = 0.7504 + 1.1587 \log K_{ow}$	.98	$7.0 - 1.6\times10^{4}$
K_{ow}	$\log CF = 0.7285 + 0.6335 \log K_{ow}$	.79	$1.6 - 1.4\times10^{4}$
K_{ow}	$\log CF = 0.124 + 0.542 \log K_{ow}$	.95	$4.4\times100 - 4.2\times10^{7}$
K_{ow}	$\log CF = -1.495 + 0.935 \log K_{ow}$	.87	$1.6\times100 - 3.7\times10^{6}$
K_{ow}	$\log CF = -0.70 + 0.85 \log K_{ow}$	.95	$1.0 - 1.0\times10^{7}$
K_{ow}	$\log CF = 0.124 + 0.542 \log K_{ow}$	.90	$1.0\times100 - 5.0\times10^{7}$
S, µg/L	$\log BCF = 3.9950 - 0.3891 \log S$	.92	$1.2 - 3.7\times10^{7}$
S, µg/L	$\log BCF = 4.4806 - 0.4732 \log S$	.97	$1.3 - 4.0\times10^{7}$
S, µmol/L	$\log BCF = 3.41 - 0.508 \log S$	.96	$2.0\times10^{-2} - 5.0\times10^{3}$

3.3.4. Ecotoxicological Processes

Ecotoxicological processes differ from other ecological processes, and a review of the relevant processes and their quantitative description is therefore necessary as basis for model development. A survey of the most crucial ecotoxicological processes and the most applied mathematical descriptions of these processes is given below.

Concentration Factor. The concentration factor relates the concentration of the xenobiotic in the medium to the concentration in organisms, sediment, or suspended matter. The concentration in organisms is a result of uptake by respiration, and the concentration in sediment or suspended matter is caused by adsorption and sedimentation processes. The concentration factor *CF* can often be described with sufficient accuracy as a constant independent of the concentration in the medium (water):

$$CF = C_S / C_W \tag{86}$$

where C_S is the concentration in the organisms, suspended matter, or sediment and C_W is the concentration in water (or air). If the uptake includes the indirect route through food, the term bioconcentration factor *BCF* is often used ($BCF \geq CF$), which can be described by the same equation.

Table 21 gives equations relating water solubility and the *n*-octanol – water partition coefficient to *CF* and *BCF*. The *n*-octanol – water partition coefficient K_{ow} is defined in Section 2.4.1. An overview on relevant literature references dealing with the determination of the *n*-octanol –water partition coefficient of various chemicals in fish is given in Table 22. If the *n*-octanol –water partition coefficient is not known, it can be estimated from the water solubility of the corresponding substance (see Section 3.3.5 and Fig. 58).

Table 22. Determination of n-octanol – water partition coefficients in fish

Mosquito fish, whole	15	[450]

Biomagnification describes the process whereby pollutants are passed from one trophic level to the next and increasingly concentrated in organisms with higher trophic status (see Section 2.4.2.7). The magnification (i.e., the increasing concentration through the food chain) is caused by greater retention of toxic substances than of general food components by the organisms. The process may be described by the biological or ecological magnification factor, which indicates the magnification from one level in the food chain to the next.

Further important processes in ecological modeling are adsorption (see Section 2.4.2.4) and desorption.

Excretion of toxic substances by an organism can be shown to follow first-order kinetics to a

good approximation, and the rate coefficient depends on the chemical compound and the size of the organism considered (see [37]). This process is in most cases insignificant for the entire mass balance of the components considered but inclusion of the excretion process may be important for a model of a toxic substance on the organism level.

Biodegradation. It is rather difficult to estimate the reaction rate of biodegradation in ecotoxicology because a large number of factors influence the reaction and thereby also the concentration of microorganisms. The most important of these factors are: temperature, sorption, redox potential, ionic strength, adaptation of microbial populations, macronutrients and micronutrients available [454], [455].

Distribution of a Chemical Compound. Distribution of a chemical compound in the four spheres is of particular interest in fate models.

Distribution air – water

$$\frac{C^*}{To^*} \equiv F_{\mathrm{L}} = \frac{H18}{1000RT} \text{ (approximation)} \tag{87}$$

or at (103.33 kPa) and 20 °C

$$F_{\mathrm{L}} = 7.49 \cdot 10^{-4} H \tag{88}$$

where H is Henry's constant (bar); $C*$ and $To*$ are equilibrium concentrations (mass/volume) in air and water, respectively.

Rate of evaporation (distribution liquid – vapor phase)

$$Ev = -D \cdot A \frac{\mathrm{d}To}{\mathrm{d}x} = bK_{\mathrm{L}} \cdot A \cdot (To - To^*) \tag{89}$$

where D is the molecular diffusion coefficient (area/time), A is the area, and b is a coefficient that adjusts the evaporation coefficient K_{L} (length/time) to substances other than oxygen ($b = 1.0$ for oxygen); b can be found in [72] for other compounds. Several empirical equations for calculation of K_{L} can be found in [73], [74].

$$b = \frac{K_{\mathrm{L}}\,(\text{compound})}{K_{\mathrm{L}}\,(\text{oxygen})} = \frac{D\,(\text{compound})}{D\,(\text{oxygen})} \tag{90}$$

For lakes and streams,

$$To\,(t) = To\,(0) \cdot \mathrm{e}^{-b \cdot K_{\mathrm{L}} \cdot \mathrm{a}} \cdot t \tag{91}$$

where

$$a = \frac{A}{V} = \frac{\text{area}}{\text{volume}} \tag{92}$$

Distribution water – solid (sediment)

A distribution coefficient may be used at low concentrations (see also Langmuir's and Freundlich's adsorption isotherms):

$$F_{\mathrm{S}} = \frac{C^*}{To^*} \tag{93}$$

where $C*$ and $To*$ are the concentrations in the solid and water phases at equilibrium. Since the dimension of $C*$ is mass/mass (e.g., mg per gram dry matter) and $To*$ has the dimension of mass/volume (mg/L), F_{S} has the dimension volume/mass (L/g or L/kg).

F_{S} may be found from

$$F_{\mathrm{S}} = F_{\mathrm{oc}} \cdot f_{\mathrm{oc}} \tag{94}$$

where F_{oc} is the distribution coefficient for organic matter and f_{oc} is the fraction of organic carbon in the solid being considered.

The following relationship between F_{oc} and K_{ow} exists [456]:

$$\log F_{\mathrm{oc}} = -0.006 + 0.937 \log K_{\mathrm{ow}} \tag{95}$$

MATTER-MÜLLER et al. [457] found the following relationship for activated sludge:

$$\log F_{\mathrm{S}} = 0.39 + 0.67 \log K_{\mathrm{ow}} \tag{96}$$

where F_{S} has the units L/kg.

F_{oc} and F_{S} values for selected chemical compounds can be found in the literature.

Complex Formation. As for other chemical processes, the law of mass action is valid for complex formation reactions. For the process

$$Me^{n+} + \mathrm{L}^{m-} = \mathrm{MeL}^{(n-m)+} \tag{97}$$

(where Me denotes a metal and L a ligand), the law of mass action has the following form:

$$\frac{[MeL^{(n-m)+}]}{[\mathrm{Me}^{n+}]\,[\mathrm{L}^{m-}]} = K \tag{98}$$

K is termed the stability constant if the process – as in this case – is the formation of a complex.

The formation of coordination complexes plays a major role in modeling the distribution as well as the effect of metal ions in aquatic ecosystems because of the following influences:

1) Increase in metal solubility

$$MeY\,(S) + L = MeL + Y \tag{99}$$

where Me represents a metal that is bound in the sediment in the compound MeY; L denotes a ligand
2) Alteration of the distribution between oxidized and reduced forms of metals. The equilibrium constant for the process

$$Me^{n+} + m\mathrm{e}^- = \mathrm{Me}^{(n-m)+} \tag{100}$$

differs from the one for

$$MeL^{n+} + m\mathrm{e}^- = \mathrm{MeL}^{(n-m)+} \tag{101}$$

if the complexes, $\mathrm{MeL}^{\mathrm{n}+}$ and $\mathrm{MeL}^{(\mathrm{n}-\mathrm{m})+}$, have different stability constants, which often is the case
3) Alleviation of toxicity due to alteration of the availability to aquatic life
4) Change in adsorption and ion exchange on sediment and suspended matter
5) Change in stability of the metal-containing colloids

The presence of ligands in water generally increases the transfer of metals from sediment, soil, and suspended matter and thereby increases the solubility. However, since complexes show lower toxicity than metal ions, the harm to aquatic life in most cases does not increase in proportion to the increased solubility.

The application of coordination chemistry to environmental problems is very complex because many ligands are present in aquatic ecosystems and all ligands compete simultaneously for formation of complexes with metal ions.

Photolysis. The *Stark–Einstein law* states that if a species absorbs radiation, one particle is excited for each quantum of radiation absorbed. The energy of the particle is limited by the energy of the photon absorbed. This energy is given by

$$E = h\nu \tag{102}$$

where E is the energy of the photon, h is Planck's constant, and ν is the frequency of the photon. Thus, depending on the nature of the incident light and the property of the chromophore, different excited states of the chromophore may be formed. Although not exclusively true, in general only light absorption that brings about electronic excitation of the chromophore will result in photochemical reactions. Excitation of the vibrations and rotations of the absorbing species in its ground electronic state is less likely to induce chemical changes.

The effectiveness of photochemical reactions in the consumption or production of a given chemical species is given by the *overall quantum yield* of that process (see Section 2.4.2.2). The overall quantum yield is the number of molecules of a given reactant consumed for each photon absorbed. It may be further subdivided into the primary quantum yield (molecules consumed by primary reactions) and the secondary quantum yield (molecules consumed by secondary reactions).

If the quantum yield is not strongly wavelength dependent, for an incident beam of light with a certain spectral characteristic, the complete rate law for direct photolysis is

$$-\left(d\,[CA]\,/\mathrm{d}t\right) = k_{\mathrm{a}}\,[CA] \tag{103}$$

where CA is the concentration of the reactant and k_{a} is the sum of the k_{a} values of all the wavelengths represented by the photons in the incident light. Models for estimating the rates of direct photolysis in natural waters under restrictive conditions have been attempted by several investigators [458–466].

Acid – base reactions are of a great environmental interest because almost all processes in the environment depend on pH. A few illustrative examples are included in the following list:

1) Ammonia is toxic to fish and the ammonium : ammonia ratio depends on pH.
2) Carbon dioxide is toxic to fish and the ratio of hydrogencarbonate to carbon dioxide depends on pH.
3) The fertility of fish and zooplankton eggs is highly pH dependent.
4) All biological processes have a pH optimum, which is usually in the range 6 – 8. This implies that algal growth, microbiological decomposition, nitrification, and denitrification are all influenced by pH.

5) The release of heavy-metal ions from soil and sediment increases very rapidly with decreasing pH. Heavy-metal hydroxides have a very low solubility product, which implies that most heavy-metal ions are precipitated at pH 7.5 or higher.

Acid rain illustrates the problems related to a low pH value, but too high a pH is also of environmental concern because of items (1) and (4) above.

Other Chemical Processes. In addition, hydrolysis and redox processes may also be important for the speciation and general presence of toxic substances. Many metal hydroxides may be dissolved by hydrolysis, and the release of metal ions from lake sediments is highly dependent on the redox potential at the interface between water and sediment.

Organic compounds can also undergo hydrolysis reactions. Many compounds react with water, with introduction of a hydroxyl group into the molecule. Most toxic organic compounds are oxidized by oxygen, and carboxyl groups may be formed. For all of these reactions, a chemical pathway should be found and the application of simple first-order reaction kinetics is often sufficient to describe the process in an ecotoxicological model.

3.3.5. Parameter Estimation

About 50 000 chemicals are produced on a large scale (1000 kg or more per year), but only about 4000 chemicals are produced at a quantity of $\geq 1\times10^6$ kg/a. Approximately one-third of these chemicals are well-defined organics. Their environment-relevant properties are listed below:

Physical properties
vapor pressure, water solubility, Henry's constant, adsorption coefficient, partition coefficient octanol – water, mass-transfer coefficient, density, viscosity, diffusion coefficient in air and water, boiling and melting point

Chemical properties
rate of hydrolysis, rate of oxidation or reduction, rate of photolysis, acid dissociation coefficient(s)

Biological properties
bioconcentration factor, rate of biodegradation in soil and water under aerobic or anaerobic conditions

Most of the biological parameters are needed for all species or at least a representative fraction of the species on earth. This implies that for construction of all possible ecotoxicological models, about 20 000 parameters are needed for 50 000 chemicals (i.e., a total of ca. 1×10^9 parameters). A review of the literature reveals that hardly 1 % of these parameters, or 10×10^6 values are known. Providing the 9.9×10^8 parameters lacking will be an enormous task – a task that will take several decades to accomplish. How can ecotoxicological models be constructed under these circumstances? The answer is to estimate the parameters, which is acceptable, because ecotoxicological models do not require a high accuracy, or rather, one is forced to interpret the model results by the use of large safety factors, which makes it less necessary to demand great accuracy of the modeling results.

Many estimation methods are available for ecotoxicological parameters, and too many pages would be required to present even an overview of these methods. JØRGENSEN [37] presents a rather simple method that can be applied easily and still give sufficient accuracy for development of most ecotoxicological models.

The *physical properties* of interest in ecotoxicology are vapor pressure P, water solubility S, partition coefficient K_{ow}, and Henry's constant H; for determination of the transfer between air and water, adsorption isotherms K_{ac} and diffusion coefficients D are also necessary. For organic compounds, all these properties can be estimated just on the basis of their chemical structure. Some estimation methods are based on estimation of the boiling point and critical properties, which are then used later to estimate the aforementioned physical properties. Experience shows that generally better estimates can be given if the boiling point is known and not found by estimation methods. Simultaneous use of two or more estimation methods will always give a better overall estimation (an average value is used) than if only one method is applied. All relevant equations for the described estimation system are given in [37]. The system itself

Figure 57. Conceptual diagram of an estimation system for ecotoxicological parameters (after [37])

Figure 58. Linear regression between log K_{ow} and log S (water solubility in μmol/L), based on a range of organic compounds including aliphatic and aromatic hydrocarbons, aromatic acids, organochlorines, organophosphorus insecticides, and PCBs (after [467])

is shown conceptually in Figure 57 while the correlation between the partition coefficient *n*-octanol – water and the water solubility is given in Figure 58.

Chemical properties (i.e., rate of hydrolysis, rate of oxidation or reduction, and acid dissociation coefficients) can also be estimated.

Obviously, *biological properties* are very important in ecotoxicological modeling, and since these properties are generally even less well

known than physical and chemical properties, the estimation methods are even more important. Figure 59 shows how to estimate *CF*, *BCF*, and the ecological magnification *EM* by use of solubility data *S* and partition coefficients K_{ow}, see also the relation in Figure 60. From the structure, furthermore, biodegradation rate coefficients and toxicity can be estimated. Some of the methods work via molar mass *M* and estimations of *mp* and *bp* (see Fig. 59).

The estimation methods used in practical ecotoxicological modeling have been tested widely on compounds with known properties and have been found to have a standard deviation of 10 – 60 % for most parameters, although the standard deviations are higher for toxicological parameters. This is an acceptable accuracy since large safety factors are recommended and applied in ecotoxicological modeling. Although the number of relevant parameters that can be found in the literature is limited, review of the literature is advantageous to find the parameters that actually have been determined. Furthermore, a comparison of the parameters that have been estimated by various methods is helpful to get an idea of the accuracy of these methods for the compounds considered. The following references may be used as primary sources: [37], [47], [71], [72], [75].

3.3.6. Fugacity Models

The application of fugacity in environmental modeling has been discussed by Mackay and Paterson [215], [216]. Fugacity has the dimension of pressure and may be considered a measure of "escaping tendency" from the phase. When phases are at equilibrium, their fugacities are equal. Fugacity *f* is related to concentration by the following equation:

$$f = C/Z \tag{104}$$

where *C* is the concentration (mol/m^3) and *Z* is the fugacity capacity (mol m^{-3} Pa^{-1}). Equilibrium involves

$$C_a/C_w = Z_a/Z_w = K_p \tag{105}$$

where the indices a and w indicate air and water, respectively, as examples of the phases; K_p is a partition coefficient. Transfer rates between two phases by diffusion are expressed by the following equation (models per unit of area and time):

$$N = D \cdot \Delta f \tag{106}$$

where *N* is the rate of transfer, *D* is the diffusion coefficient, and Δf is the difference in fugacity. *D* is the total resistance for the transfer consisting of the resistances of the two phases in series. Note that *D* may be determined as $K \cdot Z$, where *K* is the transfer coefficient and *Z* is the fugacity capacity defined in Equation (104).

The so-called unit world model consists of six compartments: air, water, soil, sediment, suspended sediment, and biota. This simplified model aims at identification of the partition of toxic substances emitted to the environment among these six compartments. The conceptual diagram of the unit world model is shown in Figure 61.

The fugacity model may be used at four levels. The *first level* calculates the equilibrium distribution of a chemical between phases. It assumes that each compartment is well mixed, and no reaction or advection into or out of the system occurs.

If *M* is the total amount of a chemical in moles, m_i and V_i are the amounts of the chemical and the volumes in each compartment, then:

$$M = \sum m_i = \sum C_i \cdot V_i = \sum f_i \cdot Z_i \cdot V_i = f \cdot \sum Z_i \cdot V_i \tag{107}$$

Since *M* is known, *f* may be calculated and the amount of substance in each compartment is given by

$$m_i = f \cdot V_i \cdot Z_i \tag{108}$$

The percentage distribution is found as m_i/M and the concentrations are found by

$$C_i = Z_i \cdot f \tag{109}$$

Level two considers equilibrium but includes reaction and advection as well. Reactions comprise photolysis, hydrolysis, biodegradation, oxidation, and so on. All the processes are assumed to be first-order reactions. If the rate constants are not known or cannot be estimated, they are set to zero. Since process rates are expressed in first-order form, they are additive and the total

Figure 59. General structure – activity relationships of potentially toxic substances

Figure 60. Relationship between log K_{OW} and log BCF, valid for fish ca. 25 cm in length

Figure 61. Conceptual diagram of fugacity models

removal rate of a chemical from a compartment is

$$\sum V_i \cdot C_i \cdot \sum k_j = \sum V_i \cdot C_i \cdot k_i \tag{110}$$

where k_j and k_i denote the rate constants of conversion of substances j and i.

As in level one, a common fugacity f prevails, and if $f \cdot Z$ is substituted for C the total rate E is

$$E = f \cdot \sum V_i \cdot Z_i \cdot k_i \tag{111}$$

The average residence time due to reactions t_r may be found by use of the following equation:

$$t_r = M/E \tag{112}$$

and the overall rate constant K is E/M or $1/t_r$.

The *third level* is devoted to a steady-state, nonequilibrium situation, which implies that the fugacities are different in each phase. Equation (105) is used to account for the transfer. The D values may be calculated from quantities such as interface areas, mass-transfer coefficients (as indicated above, D is the product of the transfer coefficient and the fugacity capacity: $D = K \cdot Z$), release rate of chemicals into phases such as biota or sediment, and Z values, or by use of the estimation methods presented in Section 3.3.5.

Level four involves a dynamic version of level three where emissions, and thus concentrations, vary with time. This implies that differential equations must be applied for each compartment to calculate the change in concentrations with time, for instance:

$$V_i \cdot \mathrm{d}C_i/\mathrm{d}t = E_i - V_i \cdot C_i \cdot k_i - \sum D_{ij} \cdot \Delta f_{ij} \tag{113}$$

This model level is similar in concept to the EXAMS model [251].

Levels one and two are sufficient in most cases, but if the environmental management problem requires the prediction of (1) the time required for a substance to accumulate to a certain concentration in a phase after emission has started, or (2) the length of time for the system to recover after the emission has ceased, the fourth level must be applied.

This approach has been used widely, and a typical example is given by MACKAY et al. [251]. It concerns the distribution of PCB between air

and water in the Great Lakes. In this case, H was 49.1 bar and the air – water distribution coefficient ($=H/RT$) 0.02. The fugacity capacity for water ($=1/H$) was found to be 0.0204 bar and the fugacity capacity for air ($=1/RT$) 0.000404 bar. The distribution coefficient of PCB between water and suspended matter in the water was estimated to be 100 000. Since the concentration of suspended matter in the Great Lakes has been found to be 2×10^{-6} on a volume basis (approximately 4 mg/L) the fraction dissolved was $1/(1+0.2)=0.833$.

The PCB concentration in water of the Great Lakes was 2 ng/L, and in the air 2 ng/m^3. The fugacity can be calculated in water and air as C/Z, and the fugacity in water was found to be 17 times higher than in air, which implies that volatilization will occur. If the transfer coefficient in water is assumed to be 10^{-5} m/s and in air 10^{-3} m/s, the volatilization rate can be calculated from the traditional two-resistance model, using the relation $D=K\cdot Z$ to find the overall diffusion coefficient, D:

$$1/D = 1/10^{-5}\cdot 0.0204\,\mathrm{bar} + 1/10^{-3}\cdot 0.000404\,\mathrm{bar} \tag{114}$$

D is 1.36×10^{-7}; N is calculated by use of Equation (106):

$$N = D\,(f_{\mathrm{w}} - f_{\mathrm{a}}) = D\left(2.8\times10^{-7}\,\mathrm{Pa} - 1.53\times10^{-8}\,\mathrm{Pa}\right) \tag{115}$$

N is found to be 35.9×10^{-15} mol m^{-2} s^{-1}.

The transfer with precipitation is negligible compared to the volatilization rate, while the washout of particles and dry deposition are important processes. If these processes are considered, the net flux to the atmosphere becomes about 75 % of the flux found above.

4. Appendix [291]

Risk Assessment Directive 93/67/EEC	Document XI/730/89 rev. 3 (Ispra)	Notes
Risk Assessment		
A generic term describing an administrative and technical process that entails some or all of the elements below	no equivalent term	much wider meaning of the term than at Ispra
Effects Assessment		
1) Hazard Identification	Hazard Identification	these two terms are synonymous
Identification of the adverse effects a substance has an inherent capacity to cause; and, where possible or appropriate, assessment of a particular effect		they describe inherent properties
2) Dose – response assessment		
Estimation of the relationship between dose (or level of exposure) and the incidence and severity of an effect		
Exposure assessment	Hazard assessment (part only)	
Determination of the emissions, pathways, and rates of movement of a substance and its transformation or deradation in order to estimate the concentrations/doses to which human populations or environmental compartments are or may be exposed	= ″environmental exposure″	this part of hazard assessment (Ispra) is synonymous with exposure assessment (draft directive)
		leads to PEC
	Hazard assessment (part only) = ″effect data with reference to the environmental compartment of concern″	this is aided by a knowledge of hazard identification (Ispra)
		eads to PEC
Effects assessment plus exposure assessment	Hazard assessment	synonymous terms
		comparison of PEC and PNEC
Risk characterization	Risk assessment (see below) plus hazard assessment	synonymous terms, i.e., PEC : PNEC ratios against a probability scale
Estimation of the incidence and severity of the adverse effects likely to occur in a human population or environmental compartment due to actual or predicted exposure to a substance and may include		
Risk estimation	Risk assessment	synonymous terms
Quantification of the likelihood of the incidence and severity of the adverse effects	estimation of the probability that a substance causes adverse effects as a result of its presence in the environment at a given concentration	
Risk reduction	Risk management	synonymous terms , e.g., special use and disposal instructions, emission control measures, restrictions on types of use, total ban of use
Measures that would enable the risks for man or the environment in connection with the marketing of the substances to be lessened	the taking of measures appropriate at least to diminish significantly the presence of a substance in the environmental compartments of concern

Abstract

The article contains sections titled:

1. Introduction
1.1. Definition and Scope
1.2. Fields
1.3. History
1.4. Information Resources
1.5. Terminology of Toxic Effects
1.6. Types of Toxic Effects
1.7. Dose-Response: a Fundamental Issue in Toxicology
1.7.1. Graphics and Calculations
1.8. Dose-Response Relationships for Cumulative Effects
1.9. Factors Influencing Dose-Response
1.9.1. Routes of Exposure
1.9.2. Frequency of Exposure
1.9.3. Species-Specific Differences in Toxicokinetics
1.9.4. Miscellaneous Factors Influencing the Magnitude of Toxic Responses
1.10. Exposure to Mixtures
2. Absorption, Distribution, Biotransformation and Elimination of Xenobiotics
2.1. Disposition of Xenobiotics
2.2. Absorption
2.2.1. Membranes
2.2.2. Penetration of Membranes by Chemicals
2.2.3. Mechanisms of Transport of Xenobiotics through Membranes
2.2.4. Absorption
2.2.4.1. Dermal Absorption
2.2.4.2. Gastrointestinal Absorption
2.2.4.3. Absorption of Xenobiotics by the Respiratory System
2.3. Distribution of Xenobiotics by Body Fluids
2.4. Storage of Xenobiotics in Organs and Tissues
2.5. Biotransformation
2.5.1. Phase-I and Phase-II Reactions
2.5.2. Localization of the Biotransformation Enzymes
2.5.3. Role of Biotransformation in Detoxication and Bioactivation
2.5.4. Phase-I Enzymes and their Reactions
2.5.4.1. Microsomal Monooxygenases: Cytochrome P450
2.5.4.2. Microsomal Monooxygenases: Flavin-Dependent Monooxygenases
2.5.4.3. Peroxidative Biotransformation: Prostaglandin-synthase
2.5.4.4. Nonmicrosomal Oxidations
2.5.4.5. Hydrolytic Enzymes in Phase-I Biotransformation Reactions
2.5.5. Phase-II Biotransformation Enzymes and their Reactions
2.5.5.1. UDP-Glucuronyl Transferases
2.5.5.2. Sulfate Conjugation
2.5.5.3. Methyl Transferases
2.5.5.4. *N*-Acetyl Transferases
2.5.5.5. Amino Acid Conjugation
2.5.5.6. Glutathione Conjugation of Xenobiotics and Mercapturic Acid Excretion
2.5.6. Bioactivation of Xenobiotics
2.5.6.1. Formation of Stable but Toxic Metabolites
2.5.6.2. Biotransformation to Reactive Electrophiles
2.5.6.3. Biotransformation of Xenobiotics to Radicals
2.5.6.4. Formation of Reactive Oxygen Metabolites by Xenobiotics
2.5.6.5. Detoxication and Interactions of Reactive Metabolites with Cellular Macromolecules
2.5.6.6. Interaction of Reactive Intermediates with Cellular Macromolecules
2.5.7. Factors Modifying Biotransformation and Bioactivation
2.5.7.1. Host Factors Affecting Biotransformation
2.5.7.2. Chemical-Related Factors that Influence Biotransformation
2.5.8. Elimination of Xenobiotics and their Metabolites
2.5.8.1. Renal Excretion
2.5.8.2. Hepatic Excretion

2.5.8.3. Xenobiotic Elimination by the Lungs
2.6. Toxicokinetics
2.6.1. Pharmacokinetic Models
2.6.1.1. One-Compartment Model
2.6.1.2. Two-Compartment Model
2.6.2. Physiologically Based Pharmacokinetic Models
3. Mechanisms of Acute and Chronic Toxicity and Mechanisms of Chemical Carcinogenesis
3.1. Biochemical Basis of Toxicology
3.2. Receptor-Ligand Interactions
3.2.1. Basic Interactions
3.2.2. Interference with Excitable Membrane Functions
3.2.3. Interference of Xenobiotics with Oxygen Transport, Cellular Oxygen Utilization, and Energy Production
3.3. Binding of Xenobiotics to Biomolecules
3.3.1. Binding of Xenobiotics or their Metabolites to Cellular Proteins
3.3.2. Interaction of Xenobiotics or their Metabolites with Lipid Constituents
3.3.3. Interactions of Xenobiotics or their Metabolites with nucleic Acids
3.4. Perturbation of Calcium Homeostasis by Xenobiotics or their Metabolites
3.5. Nonlethal Genetic Alterations in Somatic Cells and Carcinogenesis
3.6. DNA Structure and Function
3.6.1. DNA Structure
3.6.2. Transcription
3.6.3. Translation
3.6.4. Regulation of Gene Expression
3.6.5. DNA Repair
3.7. Molecular Mechanisms of Malignant Transformation and Tumor Formation
3.7.1. Mutations
3.7.2. Causal Link between Mutation and Cancer
3.7.3. Proto-Oncogenes and Tumor-Suppressor Genes as Genetic Targets
3.7.4. Genotoxic versus Nongenotoxic Mechanisms of Carcinogenesis
3.8. Mechanisms of Chemically Induced Reproductive and Developmental Toxicity
3.8.1. Embryotoxicity, Teratogenesis, and Transplacental Carcinogenesis
3.8.2. Patterns of Dose-Response in Teratogenesis, Embryotoxicity, and Embryolethality
4. Methods in Toxicology
4.1. Toxicological Studies: General Aspects
4.2. Acute Toxicity
4.2.1. Testing for Acute Toxicity by the Oral Route: LD_{50} Test and Fixed-Dose Method
4.2.2. Testing for Acute Skin Toxicity
4.2.3. Testing for Acute Toxicity by Inhalation
4.3. Repeated-Dose Toxicity Studies: Subacute, Subchronic and Chronic Studies
4.4. Ophtalmic Toxicity
4.5. Sensitization Testing
4.6. Phototoxicity and Photosensitization Testing
4.7. Reproductive and Developmental Toxicity Tests
4.7.1. Fertility and General Reproductive Performance
4.7.2. Embryotoxicity and Teratogenicity

5.2. The Risk Assessment Process
5.2.1. Hazard Identification Techniques
5.2.2. Determination of Exposure
5.2.3. Dose-Response Relationships
5.2.4. Risk Characterization
5.2.4.1. The Safety-Factor Methodology
5.2.4.2. Risk Estimation Techniques for Nonthreshold Effects
5.2.4.3. Mathematical Models Used in High- to Low-Dose Risk Extrapolation
5.2.4.4. Interpretation of Data from Chronic Animal Bioassays
5.2.4.5. Problems and Uncertainties in Risk Assessment
5.3. Future Contributions of Scientifically Based Procedures to Risk Assessment and Qualitative Risk Assessment for Carcinogens
5.4. Risk Assessment for Teratogens

[Top of Page]

1. Introduction

1.1. Definition and Scope

Chemicals that are used or of potential use in commerce, the home, the environment, and medical practice may present various types of harmful effects. The nature of these effects is determined by the physicochemical characteristics of the agent, its ability to interact with biological systems (hazard), and its potential to come into contact with biological systems (exposure).

Toxicology studies the interaction between chemicals and biological systems to determine the potential of chemicals to produce adverse effects in living organisms. Toxicology also investigates the nature, incidence, mechanisms of production, factors influencing their development, and reversibility of such adverse effects. Adverse effects are defined as detrimental to the survival or the normal functioning of the individual. Inherent in this definition are the following key issues in toxicology:

1. Chemicals must come into close structural and/or functional contact with tissues or organs to cause injury.
2. All adverse effects depend on the amount of chemical in contact with the biological system (the dose) and the inherent toxicity of the chemical (hazard). When possible, the observed toxic effect should be related to the degree of exposure. The influence of different exposure doses on the magnitude and incidence of the toxic effect should be quantitated. Such dose-response relationships are of prime importance in confirming a causal relationship between chemical exposure and toxic effect (for details, see Section Dose–Response: a Fundamental Issue in Toxicology).

Research in toxicology is mainly concerned with determining the potential for adverse effects caused by chemicals, both natural and synthetic, to assess their hazard and risk of human exposure and thus provide a basis for appropriate precautionary, protective and restrictive measures. Toxicological investigations should permit evaluation of the following characteristics of toxicity:

1. The basic structural, functional, or biochemical injury produced
2. Dose-response relationships
3. The mechanisms of toxicity (fundamental biochemical alterations responsible for the induction and maintenance of the toxic response) and reversibility of the toxic effect
4. Factors that modify response, e.g., route of exposure, species, and gender

For chemicals to which humans may potentially be exposed, a critical analysis, based on the pattern of potential exposure or toxicity, may be necessary in order to determine the risk-benefit ratio for their use in specific circumstances and to devise protective and precautionary measures. Indeed, with drugs, pesticides, food additives, and cosmetic preparations, toxicology testing must be performed in accordance with government regulations before use.

1.2. Fields

Toxicology is a recognized scientific discipline encompassing both basic and applied issues. Although only generally accepted as a specific scientific field during this century, its principles have been appreciated for centuries. The harmful or lethal effects of certain chemicals, mainly present in minerals and plants or transmitted venomous animals, have been known since prehistoric times. In many countries, toxicology as a discipline has developed from pharmacology. Pharmacology and toxicology both study the effect of chemicals on living organisms and have often used identical methods. However, fundamental differences have developed. Years ago, only the dependence on dose of the studied effects separated pharmacology and toxicology. Pharmacology focused on chemicals with beneficial effects (drugs) at lower doses whereas toxicology studied the adverse health effects occurring with the same chemicals at high doses. Today, the main interest of research in toxicology has shifted to studies on the long-term effects of chemicals after low-dose exposure, such as cancer or other irreversible diseases; moreover, most chemicals of interest to toxicologists are not used as drugs.

The variety of potential adverse effects and the diversity of chemicals present in our environment combine to make toxicology a very broad science. Toxicology uses basic knowledge from clinical and theoretical medicine and natural sciences such as biology and chemistry (Fig. 1). Because of this diversity, toxicologists usually specialize in certain areas.

Figure 1. Scientific fields influencing the science of toxicology

Any attempt to define the scope of toxicology must take into account that the various subdisciplines are not mutually exclusive and frequently are heavily interdependent. Due to the overlapping mechanisms of toxicity, chemical classes, and observed toxic effects, clear divisions into subjects of equal importance are often not possible.

The professional activities of toxicologists can be divided into three main categories: descriptive, mechanistic, and regulatory. The *descriptive toxicologist* is concerned directly with toxicity testing. Descriptive toxicology still often relies on the tools of pathology and clinical chemistry, but since the 1970s more mechanism-based test systems have been included in toxicity testing [1]. The appropriate toxicity tests in experimental animals yield information that is extrapolated to evaluate the risk posed by exposure to specific chemicals. The concern may be limited to effects on humans (drugs, industrial chemicals in the workplace, or food additives) or may encompass animals, plants, and other factors that might disturb the balance of the ecosystem (industrial chemicals, pesticides, environmental pollutants).

The *mechanistic toxicologist* is concerned with elucidating the mechanisms by which chemicals exert their toxic effects on living organisms. Such studies may result in the development of sensitive predictive toxicity tests useful in obtaining information for risk assessment (see Chap. Methods in Toxicology). Mechanistic studies may help in the development of chemicals that are safer to use or of more rational therapies for intoxications. In addition, an understanding of the mechanisms of toxic action also contributes to the knowledge of basic mechanisms in physiology, pharmacology, cell biology, and biochemistry. Indeed, toxic chemicals have been

used with great success as mechanistic tools to elucidate mechanisms of physiological regulation. Mechanistic toxicologists are often active in universities; however, industry and government institutions are now undertaking more and more research in mechanistic toxicology.

Regulatory toxicologists have the responsibility of deciding on the basis of data provided by the descriptive toxicologist and the mechanistic toxicologist if a drug or chemical poses a sufficiently low risk to be used for a stated purpose. Regulatory toxicologists are often active in government institutions and are involved in the establishment of standards for the amount of chemicals permitted in ambient air in the environment, in the workplace, or in drinking water. Other divisions of toxicology may be based on the classes of chemicals dealt with or application of knowledge from toxicology for a specific field (Table 1)

Table 1. Areas of toxicology

Field	Tasks and objectives
Forensic toxicology	diagnoses poisoning by analytical procedures
Pesticide toxicology	studies the safety of pesticides, develops new pesticides
Occupational toxicology	assesses potential adverse effects of chemicals used in the workplace, recommends protective procedures
Drug toxicology	studies potential effects of drugs after high doses, elucidates mechanisms of sideeffects
Regulatory toxicology	develops and interprets toxicity testing programs and is involved in controlling the use of chemicals
Environmental toxicology	studies the effects of chemicals on ecosystems and on humans after low-dose exposure from the environment

.

Forensic toxicology comprises both analytical chemistry and fundamental toxicologic principles. It is concerned with the legal aspects of the harmful effects of chemicals on humans. The expertise of the forensic toxicologist is invoked primarily to aid in establishing the cause of death and elucidating its circumstances in a postmortem investigation. The field of *clinical toxicology* recognizes and treats poisoning, both chronic and acute. Efforts are directed at treating patients poisoned by chemicals and at the development of new techniques to treat these intoxications. *Environmental toxicology* is a relatively new area that studies the effects of chemicals released by man on wildlife and the ecosystem and thus indirectly on human health.

Drug toxicology plays a major role in the preclinical safety assessment of chemicals intended for use as drugs. Drug toxicology also elucidates the mechanisms of side effects observed during clinical application. *Occupational toxicology* studies the acute and chronic toxicity of chemicals encountered in the occupational environment. Both acute and chronic occupational poisonings have exerted a major influence on the development of toxicology in general. Occupational toxicology also helps in the development of safety procedures to prevent intoxications in the workplace and assists in the definition of exposure limits. *Pesticide toxicology* is involved in the development of new pesticides and the safety of pesticide formulations. Pesticide toxicology also characterizes potential health risks to the general population caused by pesticide residues in food and drinking water.

1.3. History

Toxicology must rank as one of the oldest practical sciences because humans, from the very beginning, needed to avoid the numerous toxic plants and animals in their environment. The presence of toxic agents in animals and plants was known to the Egyptian and Greek civilisations. The papyrus Ebers, an Egyptian papyrus dating from about 1 500 B.C., and the surviving medical works of HIPPOCRATES, ARISTOTLE, and THEOPHRASTUS, published during the period 400–250 B.C., all included some mention of poisons.

The Greek and Roman civilizations knowingly used certain toxic chemicals and extracts for hunting, warfare, suicide, and murder. Up to the Middle Ages, toxicology was restricted to the use of toxic agents for murder. Poisoning was developed to an art in medieval Italy and has remained a problem ever since, and much of the earlier impetus for the development of toxicology was primarily forensic. There appear to have been few advances in either medicine or toxicology between the time of GALEN (131–200 A.D.) and PARACELSUS (1493–1541). The latter laid the groundwork for the later development of modern toxicology. He clearly was aware of the dose–response relationship. His statement that “All substances are poisons; there is none that is not a poison. The right dose differentiates a poison and a remedy,” is properly regarded as a landmark in the development of the science of toxicology. His belief in the value of experimentation also represents a break with much earlier tradition. Important developments in the 1700s include the publication of RAMAZZINI's *Diseases of Workers*, which led to his recognition as the father of occupational medicine. The correlation between the occupation of chimney sweepers and scrotal cancer by POTT in 1775 is also noteworthy.

ORFILA, a Spaniard working at the University of Paris, clearly identified toxicology as a separate science and wrote the first book devoted exclusively to it (1815). Workers of the later 1800s who produced treatises on toxicology include CHRISTISON, KOBERT, and LEWIN. They increased our knowledge of the chemistry of poisons, the treatment of poisoning, the analysis of both xenobiotics and toxicity, as well as modes of action and detoxication. A major impetus for toxicology in the 1900s was the use of chemicals for warfare. In World War I, a variety of poisonous chemicals were used in the battlefields of France. This provided stimulus for work on mechanisms of toxicity as well as medical countermeasures to poisoning. Since the 1960s, toxicology has entered a phase of rapid development and has changed from a science that was almost entirely descriptive to one in which the study of mechanisms has become the prime task. The many reasons for this include the development of new analytical methods since 1945, the emphasis on drug testing following the thalidomide tragedy, the emphasis on pesticide testing following the publication of Rachel Carson's *Silent Spring* and public concern over environmental pollution and disposal of hazardous waste.

1.4. Information Resources

Because of the complexity of toxicology as a science and the impact of toxicological investigations on legislation and commerce, a wide range of information on the toxic effects of chemicals is available. No single, exhaustive source of toxicological data exists; several sources are required to obtain comprehensive information on a particular chemical. Printed sources are often quicker and easier to use than computer data bases, but interactive online searching can rapidly gather important information from the huge number of sources present.

The information explosion in toxicology has resulted in a comprehensive volume dedicated to toxicological information sources:

P. Wexler, P. J. Hakkinen, G. Kennedy, Jr. F. W.Stoss, *Information Resources in Toxicology*, 3rd ed., Academic Press, 1999.

Textbooks. The easiest way to obtain information on general topics in toxicology and secondary references are a range of textbooks available on the market. Only a few selected books are listed below:

C. D. Klaasen, *Casarett and Doull's Toxicology; The Basic Science of Poisons*, 6th ed., McGraw-Hill, New York, 2001.
G. D. Clayton, F. E. Clayton (eds): *Patty's Industrial Hygiene and Toxicology*, Wiley, New York, 1993.
J. G. Hardman, L. E. Limbird, *Goodman and Gilman's, The Pharmacological Basis of Therapeutics*, 10th ed., McGraw-Hill, New York, 2001.
W. A. Hayes, *Principles and Methods of Toxicology*, 3rd ed., Raven Press, New York, 2001.
E. Hodgson (Ed.): *Textbook of Modern Toxicology*, 3rd ed., Wiley Interscience, 2004.
T. A. Loomis, A. W. Hayes, *Loomis's Essentials of Toxicology*, 4th ed., Academic Press, San Diego, 1996.

The huge volume by N. I. Sax and R. J. Lewis, *Dangerous Properties of Industrial Materials*, 7th ed.,Wiley, New York, 1999, contains basic toxicological data on a large selection of chemicals (almost 20 000) and may serve as a useful guide to the literature for compounds not covered in other publications.

Monographs. The best summary information on toxicology is published in the form of series by governments and international organizations. Most of these series are summarizing the results of toxicity studies on specific chemicals. The selection of these chemicals is mainly based on the extent of their use in industry (e.g. trichloroethene), their occurrence as environmental contaminants (mercury) or their extraordinary toxicity (e.g. 2,3,7,8-tetrachlorodibenzodioxin):

American Conference of Governmental Industrial Hygienists, Threshold Limit Values and Biological Exposure Indices (Cincinnati, OH). Published annually. MAK-Begründungen, VCH Publishers, Weinheim, Federal Republic of Germany. This German series includes detailed information on the toxicity of chemicals on the German MAK list (ca. 150 reports are available; the series is continuously expanded).

The Commission of the European Communities publishes the Reports of the Scientific Committee on Cosmetology and the Reports of the Scientific Committee for Food.

The Environmental Protection Agency (EPA) publishes a huge number of reports and toxicological profiles. They are indexed in “EPA Publications. A Quarterly Guide.”

The European Chemical Industry Ecology and Toxicology Centre (ECETOC) issues “Monographs” (more than 20 have been published) and “Joint Assessments of Commodity Chemicals.”

The monographs of the International Agency for Research on Cancer are definitive evaluations of carcinogenic hazards. The “Environmental Health Criteria” documents of the International Programme on Chemical Safety (IPCS) assess environmental and human health effects of exposure to chemicals, and biological or physical agents. A related “Health and Safety Guide” series give guidance on setting exposure limits for national chemical safety programs.

The National Institute for Occupational Safety and Health (NIOSH), has published 50 “Current Intelligence Bulletins” on health hazards of materials and processes at work.

The technical report series of the National Toxicology Program (NTP) reports results of their carcinogenicity bioassays, which include summaries of the toxicology of the chemicals studied. A status report indexes both studies that are under way and those that have been published. The program also issues an “Annual Review of Current DHHS [U.S. Department of Health and Human Services], DOE [U.S. Department of Energy] and EPA Research” related to toxicology.

A large number of internet-based resources are also available to collect information on toxic effects of chemicals and methods for risk assessment. Some information sites containing large amounts of downloadable information are listed below:

US Environmental Protection Agency (EPA), Integrated Risk Information System (IRIS), http://www.epa.gov/iris/index.html
US Environmental Protection Agency (EPA), ECOTOX Database, http://www.epa.gov/ecotox/
Organisation for Economic Co-operation and Development (OECD), test guidelines, http://www.oecd.org
Agency for Toxic Substances and Disease Registry (ATSDR), toxicological profile information sheet http://www.atsdr.cdc.gov/toxprofiles/
European Chemicals Bureau, http://ecb.jrc.it/
National Toxicology Programm, http://ntp-server.niehs.nih.gov/htdocs/liason/Factsheets/FactsheetList.html
United Nations Environment Programm, Chemicals http://www.chem.unep.ch/

Journals Results of toxicological research are published in more than 100 journals. Those listed below mainly publish research closely related to toxicology, but articles of relevance may also be found in other biomedical journals:

Databases and Databanks. Electronic sources, such as computer data bases or CD-ROM are a fast and convenient way to obtain references on the toxicity of chemicals. Since on-line searching of commercial data bases such as STN-International may be expensive, CD-ROM-based systems are increasingly being used. The major advantages are speed, the ability to refine searches and format the results, and non-text search options, such as chemical structure searching on Beilstein and Chemical Abstracts.

Useful information about actual research on the toxicology of chemicals may be obtained by searching Chemical Abstracts or Medline with the appropriate keywords. Specific data banks covering toxicology are the Registry of Toxic Effects of Chemical Substances, which gives summary data, statistics, and structures; Toxline (available in DIMDI) gives access to the literature.

1.5. Terminology of Toxic Effects

Toxic effects may be divided according to timescale (acute and delayed), general locus of action (local, systemic, organ specific), or basic mechanisms of toxicity (reversible versus irreversible). *Acute toxic effects* are those that occur after brief exposure to a chemical. Acute toxic effects usually develop rapidly after single or multiple administrations of a chemical; however, acute exposure may also produce *delayed toxicity*. For example, inhalation of a lethal dose of HCN causes death in less than a minute, whereas lethal doses of 2,3,7,8-tetrachlorodibenzodioxin will result in the death of experimental animals after more than two weeks. *Chronic effects* are those that appear after repetitive exposure to a substance; many compounds require several months of continuous exposure to produce adverse effects. Often, the chronic effects of chemicals are different from those seen after acute exposure (Table 2). For example, inhalation of chloroform for a short period of time may cause anesthesia; long-term inhalation of much lower chloroform concentrations causes liver damage. Carcinogenic effects of chemicals usually have a long latency period; tumors may be observed years (in rodents) or even decades (in humans) after exposure.

Table 2. Toxic effects of different chemicals categorized by time scale and general locus of action

Exposure	Site	Effect	Chemical
Acute	local	lung edema	chlorine gas
	systemic	liver damage	carbon tetrachloride
		narcosis	halothane
Subchronic	local	sensitization	toluene diisocyanate
	systemic	neurotoxicity	hexane
Chronic	local	bronchitis	sulfur dioxide
		nasal carcinoma	formaldehyde
	systemic	bladder carcinoma	4-amino-biphenyl
		kidney damage	cadmium

Toxic effects of chemicals may also be classified based on the type of interaction between the chemical and the organism. Toxic effects may be caused by reversible and irreversible interactions (Table 3). When reversible interactions are responsible for toxic effects, the concentration of the chemical present at the site of action is the only determinant of toxic outcome. When the concentration of the xenobiotic is decreased by excretion or biotransformation, a parallel decrease of toxic effects is

observed.

Table 3. Reversible and irreversible interactions of chemicals with cellular macromolecules as a basis for toxic response

Mechanism	Toxic response	Example
Irreversible inhibition of		
Esterase	neurotoxicity	tri-*o*-cresylphosphate
Covalent binding to DNA	cancer	dimethylnitrosamine
Reversible binding to		
Hemoglobin	oxygen deprivation in tissues	carbon monoxide
Cholinesterase	neurotoxicity	carbamate pesticides

After complete excretion of the toxic agent, toxic effects are reduced to zero (see below). A classical example for reversible toxic effects is carbon monoxide. Carbon monoxide binds to hemoglobin and, due to the formation of the stable hemoglobin–carbon monoxide complex, binding of oxygen is blocked. As a result of the impaired oxygen transport in blood from the lung, tissue oxygen concentrations are reduced and cells sensitive to oxygen deprivation will die. The toxic effects of carbon monoxide are directly correlated with the extent of carboxyhemoglobin in blood, the concentration of which is dependent on the inhaled concentration of carbon monoxide. After exhalation of carbon monoxide and survival of the acute intoxication, no toxic effect remains (Fig. 2).

Figure 2. Reversible binding of carbon monoxide to hemoglobin and inhibition of oxygen transport

Irreversible toxic effects are often caused by the covalent binding of toxic chemicals to biological macromolecules. Under extreme conditions, the modified macromolecule is not repaired; after excretion of the toxic agent, the effect persists. Further exposure to the toxic agent will produce additive effects; many chemicals carcinogens are believed to act through irreversible changes (see Section Bioactivation of Xenobiotics).

Another distinction between types of effects may be made according to the general locus of action. *Local toxicity* occurs at the site of first contact between the biological system and the toxic agent. Local effects to the skin, the respiratory tract, or the alimentary tract may be produced by skin contact with a corrosive agent, by inhalation of irritant gases, or by ingestion of tissue-damaging materials. This type of toxic responses is usually restricted to the tissues with direct contact to the agent. However, life-threatening intoxications may occur if vital organs like the lung are damaged. For example, inhaled phosgene damages the alveoli of the lung and causes lung edema. The massive damage to the lung results in the substantial mortality observed after phosgene intoxication.

The opposite to local effects are *systemic effects*. They are characterized by the absorption of the chemical and distribution from the port of entry to a distant site where toxic effects are produced. Except for highly reactive xenobiotics, which mainly act locally, most chemicals act systemically. Many chemicals that produce systemic toxicity only cause damage to certain organs, tissues, or cell types within organs. Selective damage to certain organs or tissues by systemically distributed chemicals is termed organ- or tissue-specific toxicity [2]; the organs damaged are referred to as target organs (Table 4).

Table 4. Organ-specific toxic effects induced by chemicals that are distributed systemically in the organism

Chemical	Species	Target organ
Benzene	humans	bone marrow
Hexachlorobutadiene	rodents	damage to proximal tubules of the kidney
Paraquat	rodents, humans	lung
Tri-*o*-cresylphosphate	humans	nervous system
Cadmium	humans	kidney
1,2-Dibromo-3-chloropropane	humans, rodents	testes
Hexane	rodents, humans	nervous system
Anthracyclines	humans	heart

Major target organs for toxic effects are the central nervous system and the circulatory system followed by the blood and hematopoietic system and visceral organs such as the liver or the kidney. For some chemicals, both local and systemic effects can be demonstrated; moreover, chemicals producing marked local toxicity may also cause systemic effects as secondary responses to major disturbances in homeostasis of the organism.

1.6. Types of Toxic Effects

The spectrum of toxic effects of chemicals is broad, and their magnitude and nature depend on many factors such as the physiocochemical properties of the chemical and its toxicokinetics, the conditions of exposure, and the presence of adaptive and protective mechanisms. The latter factors include physiological mechanisms such as adaptive enzyme induction, DNA repair, and others. Toxic effects may be transient, reversible, or irrversible; some are deleterious and others are not. Toxic effects may take the form of tissue pathology, aberrant growth processes, or altered biochemical pathways. Some of the more frequently encountered types of injury constituting a toxic response are described in the following.

Immune-mediated hypersensitivity reactions by antigenic materials are toxic effects often involved in skin and lung injury by repeated contact to chemicals resulting in contact dermatitis and asthma. Inflammation is a frequently observed local response to the application of irritant chemicals or may be a component of systemic injury. This response may be acute with irritant or tissue damaging materials or chronic with repetitive exposure to irritants. Necrosis, that is, death of cells or tissues, may be the result of various pathological processes resulting from biochemical interactions of xenobiotics, as described in Chapter 3. The extent and patterns of necrosis may be different for different chemicals, even in the same organ. Chemical tumorigenesis or carcinogenesis (induction of malignant tumors) is an effect often observed after chronic application of chemicals. Due the long latency period and the poor prognosis for individuals diagnosed with cancer, studies to predict the potential tumorigenicity of chemicals have developed into a major area of toxicological research. Developmental and reproductive toxicology are concerned with adverse effects on the ability to conceive, and with adverse effects on the structural and functional integrity of the fetus. Chemicals may interfere with reproduction through direct effects on reproductive organs or indirectly by affecting their neural and endocrine control mechansims. Developmental toxicity deals with adverse effects on the conceptus through all stages of pregnancy. Damage to the fetus may result in embryo reabsorption, fetal death, or abortion. Nonlethal fetotoxicity may be expressed as delayed maturation, decreased birth weight, or structural malformation. The most sensitive period for the induction of malformation is during organogenesis; neurobehavioral malformations may be induced during later stages of pregnancy.

1.7. Dose–Response: a Fundamental Issue in Toxicology

In principle, a poison is a chemical that has an adverse effect on a living organism. However, this is not a useful definition since toxic effects are related to dose. The definition of a poison thus also involves quantitative biological aspects. At sufficiently high doses, any chemical may be toxic. The importance of dose is clearly seen with molecular oxygen or dietary metals. Oxygen at a concentration of 21% in the atmosphere is essential for life, but 100% oxygen at atmospheric pressure causes massive lung injury in rodents and often results in death. Some metals such as iron, copper, and zinc are essential nutrients. When they are present in insufficient amounts in the human diet, specific disease patterns develop, but in high doses they can cause fatal intoxications. Toxic compounds are not restricted to man-made

chemicals, but also include many naturally occurring chemicals. Indeed, the agent with the highest toxicity is a natural poison found in the bacterium *Clostridium botulinum* (LD_{50} 0.01 µ/kg).

Therefore, all toxic effects are products of the amount of chemical to which the organism is exposed and the inherent toxicity of the chemical; they also depend on the sensitivity of the biological system.

The term “dose” is most frequently used to characterize the total amount of material to which an organism is exposed; dose defines the amount of chemical given in relation to body weight. Dose is a more meaningful and comparative indicator of exposure than the term exposure itself. Dose usually implies the exposure dose, the total amount of chemical administered to an organism or incorporated into a test system. However, dose may not be directly proportional to the toxic effects since toxicity depends on the amount of chemical absorbed. Usually, dose correctly describes only the actual amount of chemical absorbed when the chemical is administered orally or by injection. Under these circumstances, the administered dose is identical to the absorbed dose; other routes of application such as dermal application or inhalation do not define the amount of agent absorbed.

Different chemicals have a wide spectrum of doses needed to induce toxic effects or death. To characterize the acute toxicity of different chemicals, LD_{50} values are frequently used as a basis for comparisons. Some LD_{50} values (rat) for a range of chemicals follow:

Ethanol	12 500
Sodium bicarbonate	4 220
Phenobarbital sodium	350
Paraquat	120
Aldrin	46
Sodium cyanide	6.4
Strychnine	5
1,2-Dibromoethane	0.4
Sodium fluoroacetate	0.2
2,3,7,8-Tetrachlorodibenzodioxin	0.01

Certain chemicals are very toxic and produce death after administration of microgram doses, while others are tolerated without serious toxicity in gram doses. The above data clearly demonstrate that the toxicity of a specific chemical is related to dose. The dependence of the toxic effects of a specific chemical on dose is termed dose–response relationship. Before dose–response relationships can be appropriately used, several basic assumptions must be considered. The first is that the response is due to the chemical administered. It is usually assumed that the responses observed were a result of the various doses of chemical administered. Under experimental conditions, the toxic response usually is correlated to the chemical administered, since both exposure and effect are well defined and can be quantified. However, it is not always apparent that the response is the result of specific chemical exposure. For example, an epidemiologic study might result in discovery of an “association” between a response (e.g., disease) and one or more variables including the estimated dose of a chemical. The true doses to which individuals have been exposed are often estimates, and the specificity of the response for that chemical is doubtful.

Further major necessary assumptions in establishing dose–response relationships are:

- A molecular site (often termed receptor) with which the chemical interacts to produce the response. Receptors are macromolecular components of tissues with which a chemical interacts and produces its characteristic effect.
- The production of a response and the degree of the response are related to the concentration of the agent at the receptor.
- The concentration of the chemical at the receptor is related to the dose administered. Since in most cases the concentration of an administered chemical at the receptor cannot be determined, the administered dose or the blood level of the chemical is used as an indicator for its concentration at the molecular site.

A further prerequisite for using the dose–response relationship is that the toxic response can be exactly measured. A great variety of criteria or end points of toxicity may be used. The ideal end point should be closely associated with the molecular events resulting from exposure to the toxin and should be readily determined. However, although many end points are quantitative and precise, they are often only indirect measures of toxicity. For example, changes in enzyme levels in the blood can be indicative of tissue damage. Patterns of alterations may provide insight into which organ or system is the site of toxic effects. These measures usually are not directly related to the mechanism of toxic action. The dose–response relationship combines the characteristic of exposure and the inherent toxicity of the chemical. Since toxic responses to a chemical are usually functions of both time and dose, in typical dose–response relationships, the maximum effect observed during the time of observation is plotted against the dose to give time-independent curves. The time-independent dose–response relationship may be used to study dose–response for both reversible and irreversible toxic effects. However, in risk assessments that consider the induction of irreversible effects such as cancer, the time factor plays a major role and has important influences on the magnitude or likelihood of toxic responses. Thus, for this type of mechanism of toxic action, dose–time–response relationships are better descriptors of toxic effects.

The dose–response relationship is the most fundamental concept in toxicology. Indeed, an understanding of this relationship is essential for the study of toxic chemicals.

From a practical point of view, there are two different types of dose–response relationships. Dose–response relationships may be quantal (all or nothing responses such as death) or graded. The graded or variable response involves a continual change in effect with increasing dose, for example, enzyme inhibition or changes in physiological function such as heart rate. Graded responses may be determined in an individual or in simple biochemical systems. For example, addition of increasing concentrations of 2,3,7,8-tetrachlorodibenzodioxin to cultured mammalian cells results in an increase in the concentration of a specific cytochrome P450 enzyme in the cells (for details of mechanisms, see Section Microsomal Monooxygenases: Cytochrome P450). The increase is clearly dose related and spans a wide range (Fig. 3). An example for a graded toxic effect in an individual may be inflammation caused by skin contact with an irritant material. Low doses cause slight irritation; as the amount increases, irritation turns to inflammation and the severity of inflammation increases.

Figure 3. Dose-dependent induction of cytochrome P450 1A 1 protein in cultured liver cells treated with 2,3,7,8-tetrachlorodibenzodioxin [3]

In dose–response studies in a population, a specific endpoint is also identified and the dose required to produce this end point is determined for each individual in the population. Both dose-dependent graded effects and quantal responses (death, induction of a tumor) may be investigated. With increasing amount of a chemical given to a group of animals, the magnitude of the effect and/or the number of animals affected increase. For example, if an irritant chemical is applied to the skin, as the amount of the material increases, the numbers of animals affected and the severity of inflammation increases. Quantal responses such as death induced by a potentially lethal chemical will also be dose-dependent. The dose dependency of a quantal effect in a population is based on individual differences in the response to the toxic chemical. A specific amount of the potentially lethal xenobiotic given to a group of animals may not kill all of them, but as the amount given increases, the proportion of animals killed increases.

Althought the distinctions between graded and quantal dose–response relationships are useful, the two types of responses are conceptually identical. The ordinate in both cases is simply labeled response, which may be the degree of response in an individual, or the fraction of a population responding, and the abscissa is the range of administered doses.

1.7.1. *Graphics and Calculations*

Even with a genetically homogenous population of animals of the same species and strain, the proportion of animals showing the effect will increase with dose (Fig. 4A). When the number of animals responding is plotted versus the logarithm of the dose, a typical sigmoid curve with a log-normal distribution that is symmetrical about the midpoint, is obtained (Fig. 4B).

Figure 4. Typical dose – response curves for a toxic effect

Plots are linear – linear (A); log – linear (B); and log – probit (C) for an identical set of data

When plotted on a log-linear scale, the obtained normally distributed sigmoid curve approaches a response of 0% as the dose is decreased, and 100% as the dose is increased, but theoretically never passes through 0 or 100%. Small proportions of the population at the right- and left-hand sides of the curve represent hyposusceptible and hypersusceptible members. The slope of the dose–reponse curve around the 50% value, the midpoint, gives an indication of the ranges of doses producing an effect. A steep dose–response curve indicates that the majority of the population will respond over a narrow dose range; a shallow dose–response curve indicates that a wide range of doses is required to affect the majority of the population. The curve depicted in Fig. 4 B shows that the majority of the individuals respond about the midpoint of the curve. This point is a convenient description of the average response, and is referred to as the median effective dose (ED_{50}). If mortality is the endpoint, then this dose is referred as median lethal dose (LD_{50}).

Death, a quantal response, is simple to quantify and is thus an end point incorporated in many acute toxicity studies. Lethal toxicity is usually calculated initially from specific mortality levels obtained after giving different doses of a chemical; the 50% mortality level is used most frequently since it represents the midpoint of the dose range at which the majority of deaths occur. This is the dose level that causes death of half of the population dosed. The LD_{50} values are usually given in milligrams of chemical per kilogram of body weight (from the viewpoint of chemistry and for comparison of relative potencies of different chemicals, giving the LD_{50} in moles of chemical per kilogram body weight would be desirable). After inhalation, the reference is to LC_{50} (LC = lethal concentration), which, in contrast to LD_{50} values, depends on the time of exposure; thus, it is usually expressed as *X*-hour LC_{50} value. The LD_{50} or LC_{50} values usually represent the initial information on the toxicity of a chemical and must be regarded as a first, but not a quantitative, hazard indicator that may be useful for comparison of the acute toxicity of different chemicals [3].

Similar dose–effect curves can, however, be constructed for cancer, liver injury, and other types of toxic responses. For the determination of LD_{50} values and for obtaining comparative information on dose–response curves, plotting log dose versus percent response is not practical since large numbers of animals are needed for obtaining interpretable data. Moreover, other important information on the toxicity of a chemical (e.g., LD_{05} and LD_{95}) cannot be accurately determined due to the slope of sigmoid curve. Therefore, the dose–response curve is transformed to a log-probit (probit = probability units) plot. The data in the Fig. 4B form a straight line when transformed into probit units (Fig. 4C). The EC_{50} or, if death is the end point, the LD_{50} is obtained by drawing a horizontal line from the probit unit 5, which is the 50% response point, to the dose–effect line. At the point of intersection a vertical line is drawn, and this line intersects the abscissa at the LD_{50} point. Information on the lethal dose for 90% or for 10% of the population can also be derived by a similar procedure. The confidence limits are narrowest at the midpoint of the line (LD_{50}) and are widest at the two extremes (LD_{05} and LD_{95}) of the dose–response curve. In addition to permitting determination of a numerical value for the LD_{50} of a chemical with few groups of dosed animals, the slope of the dose–response curve for comparison between toxic effects of different chemicals is obtained by the probit transformation [4].

The LD_{50} by itself, however, is an insufficient index of lethal toxicity, particularly if comparisons between different chemicals are to be made. For this purpose, all available dose–response information including the slope of the dose–response line should be used. Figure 5 demonstrates the dose–response curves for mortality for two chemicals.

Figure 5. Comparison of dose – response relationships for two chemicals (log – probit plot)

Both chemicals have identical LD_{50} values, but different slopes of the dose – response curve

The LD_{50} of both chemicals is the same (10 mg/kg). However, the slopes of the dose–response curves are quite different. Chemical A exhibits a “flat” dose–response curve: a large change in dose is required before a significant change in response will be observed. In contrast, chemical B exhibits a “steep” dose–response curve, that is, a relatively small change in dose will cause a large change in response. The chemical with the steep slope may affect a much larger proportion of the population by incremental increases in dose than chemicals having a shallow slope; thus, acute overdosing may be a problem affecting the majority of a population for chemicals with steeper slopes. Chemicals with shallower slopes may represent a problem for the hyperreactive groups at the left-hand side of the dose–response curve. Effects may occur at significantly lower dose levels then for hyperreactive groups exposed to chemicals with a steep dose–response.

While the LD_{50} values characterize the potential hazard of a chemical, the risk of an exposure is determined by the hazard multiplied by the exposure dose. Thus, even very toxic chemicals like the poison of *Clostridium botulinum* pose only a low risk; intoxications with this compound are rare since exposure is low. Moreover, acute intoxications with other highly toxic agents such as mercury salts are rarely seen, despite detectable blood levels of mercury salts in the general population, since the dose is also low. On the other hand, compounds with low toxicity may pose a definite health risk when doses are high, for example, constituents of diet or chemicals formed during food preparation by heat treatment.

Therefore, for characterizing the toxic risk of a chemical, besides information on the toxicity, information on the conditions of exposure are necessary. When using LD_{50} values for toxicity characterisation, the limitations of LD_{50} values should be explicitly noted. These limitations include methodological pitfalls influenced by

1. Strain of animal used
2. Species of animal used

and intrinsic factors limiting the use of LD_{50} values

1. Statistical method
2. No dose–response curve
3. Time to toxic effect not determined
4. No information on chronic toxicity

The most serious limitation on the use of LD_{50} values for hazard characterization are the lack of information on chronic effects of a chemical and the lack of dose–response information. Chemicals with low acute toxicity may have carcinogenic or teratogenic effects at doses that do not induce acute toxic responses. Other limitations include insufficient information on toxic effects other than lethality, the cause of death, and the time to toxic effect. Moreover, LD_{50} values are not constant, but are influenced by many factors and may differ by almost one order of magnitude when determined in different laboratories.

1.8. Dose-Response Relationships for Cumulative Effects

After chronic exposure to a chemical, toxic response may be caused by doses not showing effects after single dosing. Chronic toxic responses are often based on accumulation of either the toxic effect or of the administered chemical. Accumulation of the administered chemical is observed when the rate of elimination of the chemical is lower than the rate of administration. Since the rate of elimination is dependent on plasma concentrations, after long-term application an equilibrium concentration of the chemical in the blood is reached. Chemicals may also be stored in fat (polychlorinated pesticides such as DDT) or bone (e.g., lead). Stored chemicals usually do not cause toxic effects because of their low concentrations at the site of toxic action (receptor). After continuous application, the capacities of

the storage tissues may become saturated, and xenobiotics may then be present in higher concentration in plasma and thus at the site of action; toxic responses result. Besides cumulation of the toxic agent, the toxic effect may also cumulate (Fig. 6).

Figure 6. Accumulation of toxic chemicals based on their rate of excretion

a) The rate of excretion is equal to the rate of absorption, no accumulation occurs; b) Chemical accumulates due to a higher rate of uptake and inefficient excretion; the plasma concentrations are, however, not sufficient to exert toxic effects; c) The plasma concentrations reached after accumulation are sufficient to exert toxicity

For chemicals which irreversibly bind to macromolecules, the magnitude of toxic responses may be correlated with the total dose administered. In contrast to chemicals which act reversibly, the effect is not dependent on the frequency of dosing. Effect accumulation is often observed with carcinogens and ionizing radiation. In Figure 7 accumulation of effects is exemplified by the time- and dose-dependent induction of tumors by 4-(dimethylamino)azobenzene, a potent chemical carcinogen [5]. The TD_{50} values (50% of the treated animals carry tumors) are used to characterize the potency. Identical tumor incidences were observed after high doses and a short exposure time or after low doses and long exposure; the tumor incidence was only dependent on the total dose administered.

Figure 7. Time-dependent induction of tumors after different daily doses of 4-dimethylaminoazobenzene in rats [5]

Reversibility of toxic responses also depends on the capacity of an organ or tissue to repair injury. For example, kidney damage by xenobiotics is often, after survival of the acute phase of the intoxication, without further consequence due to the high capacity of the kidney for cell proliferation and thus the capacity to repair organ damage [6]. In contrast, injury to the central nervous system is largely irreversible since the differentiated cells of the nervous system cannot divide and dead cells cannot be replaced.

1.9. Factors Influencing Dose–Response

In animals and humans, the nature, severity, and incidence of toxic responses depend on a large number of exogenous and endogenous factors [7]. Important factors are the characteristics of exposure, the species and strain of animals used for the study, and interindividual variability in humans [8]. Toxic responses are caused by a series of complex interactions of a potentially toxic chemical with an organism. The type and magnitude of the toxic response is influenced by the concentration of the chemical at the receptor and by the type of interaction with the receptor. The concentration of a chemical at the site of action is influenced by the kinetics of uptake and elimination; since these are time-dependent phenomena, toxic responses are also time-dependent. Thus, the toxic response can be separated into two phases: toxicokinetics and toxicodynamics (Fig. 8).

Figure 8. Toxicokinetics and toxicodynamics as factors influencing the toxic response

Toxicokinetics describe the time dependency of uptake, distribution, biotransformation, and excretion of a toxic agent (a detailed description of toxicokinetics is given in Section Biotransformation). Toxicodynamics describes the interaction of the toxic agent with the receptor and thus specific interactions of the agent (see below). Toxicokinetics may be heavily influenced by species, strain, and sex and the exposure characteristics [9-13]. Differences in toxic response between species, route of exposure, and others factors are often dependent on influences on toxicokinetics. Since toxicodynamics (mechanism of action) are assumed to be identical between species, this provides the basis for a rational interspecies extrapolation of toxic effects when differences in toxicokinetics are defined.

1.9.1. *Routes of Exposure*

The primary tissue or system by which a xenobiotic comes into contact with the body, and from where it may be absorbed in order to exert systemic toxicity, is the route of exposure. The frequent circumstances of environmental exposure are ingestion (peroral), inhalation, and skin contact. Also, for investigational and therapeutic purposes, intramuscular, intravenous, and subcutaneous injections may also be routes of exposure.

The major routes by which a potentially toxic chemical can enter the body are—in descending order of effectiveness for systemic delivery—injection, inhalation, absorption from the intestinal tract, and cutaneous absorption. The relationship between route and exposure, biotransformation, and potential for toxicity, may be complex and is also influenced by the magnitude and duration of dosing (Table 5).

Table 5. Toxicity of chemicals applied by different routes of exposure (data taken from [13])

Chemical	Species	Route of application	LD_{50}, mg/kg
DDT	rat	intravenous	68
	rat	oral	113
	rat	skin contact	1931
Atropine sulfate	rat	intravenous	41
	rat	oral	620
1-Chloro-2,4-dinitrobenzene	rat	oral	1070
	rat	intraperitoneal	280
	rabbit	skin contact	130
Dieldrin	rat	oral	46
	rat	intravenous	9
	rat	skin contact	10

The route of exposure has a major influence on toxicity because of the effect of route of exposure on the bioavailability of the toxic agent. The maximum tissue levels achieved, the time to maximum tissue levels, and thus the duration of the effect are determined by the rate of absorption and the extent of distribution within the system.

Direct injection into veins is usually restricted to therapeutic applications, but it is important for the toxicology of intravenously injected drugs in addicts. Chemicals applied by intravenous injection are rapidly distributed to well-perfused organs in the blood and thus may result in the rapid induction of toxic effects. The rapid dilution of a chemical after intravenous injection by venous blood permits even the injection of locally acting or corrosive chemicals which are well tolerated. The likelihood of toxicity from inhaled chemicals depends on a number of factors, of which the physical state and properties of the agent, concentration, and time and frequency of exposure are important. Major influences on the absorption and disposition of xenobiotics are exerted by species peculiarities since the anatomy of the respiratory tract and the physiology of respiration show major differences between rodents and humans. The water solubility of a gaseous xenobiotic has a major influence on penetration into the respiratory tract. As water solubility decreases and lipid solubility increases, penetration into deeper regions of the lung, the bronchioli, and the alveoli becomes more effective. Water-soluble molecules such as formaldehyde,are effectively scavenged by the upper respiratory tract and may have toxic effects on the eye and throat. In contrast, gases with low water solubility such as phosgene may penetrate through the bronchii and bronchioli to the

alveoli. Damage to the alveolar surface may initiate a series of events that finally results in lung edema. The degree to which inhaled gases, vapors, and particulates are absorbed, and hence their potential to produce systemic toxicity, depend on their diffusion rate through the alveolar mebrane, their solubility in blood and tissue fluids, the rate of respiration, and blood flow through the capillaries.

Uptake through the alimentary tract represents an important route of exposure for xenobiotics accumulated in the food chain, for natural constituents of human diet, and, drugs. Absorption from the gastrointestinal tract is dependent on the lipophilicity of a chemical, the molecular mass of the xenobiotic, and the presence of certain dietary constituents may influence the extent and rate of absorption. Chemicals absorbed from the gastrointestinal tract are transported to the liver via the portal vein; hepatic metabolism ("hepatic first-pass effect") may efficiently reduce the concentration of the xenobiotic available in the systemic circulation after oral uptake. Compounds undergoing bioactivation in the liver usually exhibit greater toxicity when given orally than when absorbed across the respiratory tract, due to the high proportion of material passing through the liver. In contrast, chemicals causing toxicity to extrahepatic, well-perfused organs such as the kidney often show a lower degree of toxicity to extrahepatic target organs when given orally.

Skin contact is an important route of exposure in the occupational and domestic environments. Local effects may include acute inflammation and corrosion, chronic inflammatory responses, immune-mediated reactions, and neoplasia. The percutaneous absorption of materials may also be a significant route for the absorption of systemically toxic materials. Factors influencing the percutaneous absorption of substances include skin site, integrity of skin, temperature, formulation, and physicochemical characteristics, including charge, molecular mass, and hydro- and lipophilicity.

1.9.2. *Frequency of Exposure*

The exposure of experimental animals may be categorized as acute, subacute, subchronic, and chronic. Acute exposures usually last less than 24 h, and all above-mentioned routes of exposure may be applied. With chemicals of low toxicity, repeated exposures may be used. Acute inhalation exposure is usually less than 24 h; frequently 4–8 h is chosen as timescale. Repeated exposure refers to application of the chemical for less than one month (subacute), one to three months (subchronic), and more than three months (chronic). Chronic exposures to detect specific toxic effects (carcinogenicity of a chemical) may span most of the lifetime of a rodent (up to two years). Repeated exposure may be by any route; the least labor intensive route is oral, by mixing the chemical with the diet; only for specific chemicals or to simulate likely routes of exposure for humans are application in drinking water, by gastric intubation, and by inhalation applied. These are more labor-intensive and require skilled personnel and/or sophisticated techniques and thus are more expensive.

The toxic effects observed after single exposure often are different form those seen after repeated exposure. For example, inhalation of high concentration of halothane causes anesthesia in animals and humans. In contrast, long-term application of halothane in lower doses causes liver damage in sensitive species The frequency of exposure in chronic studies is important for the temporal characterisation of exposure. Chemicals with slow rates of excretion may accumulate if applied at short dosing intervals, and toxic effects may result (see Section Types of Toxic Effects). Also, a chemical producing severe effect when given in a single high dose may have no detectable effects when given in several smaller doses. Interspecies and strain differences in susceptibility to chemical-induced toxicity may be due to heterogeneity of populations, species specific physiology (for example of the respiratory system), basal metabolic rate, size- and species-specific toxicokinetics and routes of metabolism or excretion (Table 6). In some cases, animal tests may give an underestimate, in others an overestimate, of potential toxicity to humans [14].

Table 6. Comparative LD_{50} values for four different chemicals in different animal species and estimated LD_{50} for humans

Chemical	Species	LD_{50}, mg/kg
Paraquat	rat	134
	mouse	77
	guinea pig	41
	human	32 – 48
Ethanol	rat	12 500
	mouse	8000
	guinea pig	5500
	human	3500 – 5000
Acetaminophen	rat	3763
	mouse	777
	guinea pig	2968
	human	42 800
Aspirin	rat	1683
	mouse	1769
	guinea pig	1102
	human	3492

1.9.3. *Species-Specific Differences in Toxicokinetics*

Species-specific differences in toxic response are largely due to difference in toxicokinetics and biotransformation. Distribution and elimination characteristics are quite variable between species. Both qualitative and quantitative differences in biotransformation may effect the sensitivity of a given species to a toxic response (Table 7).

Table 7. Species and sex differences in the acute toxicity of 1,1-dichloroethylene after oral administration and inhalation in rats and mice (data from World Health Organization, Geneva, 1990)

Species	Dosing criteria	Estimated LD_{50}/LC_{50}
Rat, male	inhalation/4 h	7000 – 32 000 mg/L
Rat, female	inhalation/4 h	10 300 mg/L
Mouse, male	inhalation/4 h	115 mg/L
Mouse, female	inhalation/4 h	205 mg/L
Rat, male	gavage	1550 mg/kg
Rat, female	gavage	1500 mg/kg
Mouse, male	gavage	201 – 235 mg/kg
Mouse, female	gavage	171 – 221 mg/kg

For example, the elimination half-life of 2,3,7,8-tetrachlorodibenzodioxin in rats is 20 d, and in humans it is estimated to be up to seven years [15]. An example for quantitative difference in the extent of biotransformation as a factor influencing toxic response is the species differences in the biotransformation of the inhalation anesthetic halothane. Both rats and guinea pigs metabolize halothane to trifluoroacetic acid, a reaction catalyzed by a specific cytochrome P450 enzyme [16-18]. As a metabolic intermediate, trifluoroacetyl chloride is formed, which may react with lysine residues in proteins and with phosphatidyl ethanolamine in phospholipids (Fig. 9).

Figure 9. Halothane metabolism by cytochrome P450 in rats, guinea pigs, and humans

This interaction initiates a cascade of events finally resulting in toxicity. The metabolism of halothane in guinea pigs occurs at much higher rates than in rats, so guinea pigs are sensitive to halothane-induced hepatotoxic effects and rats are resistant. Qualitative differences in biotransformation are responsible for apparent differences in the sensitivity of rats and guinea pigs to the bladder carcinogenicity of 2-acetylamidofluorene. In rats, 2-acetylamidofluorene is metabolized by *N*-oxidation by certain cytochrome P450 enzymes. The *N*-oxide is further converted to an electrophilic nitrenium ion which interacts with DNA in the bladder; this biotransformation pathway explains the formation of bladder tumors in rats after long-term exposure to 2-acetylamidofluoren. In guinea pigs, 2-acetylamidofluorene is metabolized by oxidation at the aromatic ring; since nitrenium ions cannot be formed by this pathway, guinea pigs are resistant to the bladder carcinogenicity of 2-acetylamidofluorene (Fig. 10).

Figure 10. Biotransformation pathways of 2-acetylamidofluorene in rats and guinea pigs

With some chemicals, age may significantly affect toxicity, likely due to age related differences in toxicokinetics. The nutritional status may modify toxic response, likely by altering the concentration of cofactors needed for biotransformation and detoxication of toxic chemicals. Diet also markedly influences carcinogen-induced tumor incidence in animals [19] and may be a significant factor contributing to human cancer incidence.

The toxic response is influenced by the magnitude, number, and frequency of dosing. Thus, local or systemic toxicity produced by acute exposure may also occur by a cumulative process with repeated exposures to lower doses; also, additional toxicity may be seen in repeated-exposure situations. The relationships for cumulative toxicity by repetitive exposure compared with acute exposure toxicity may be complex, and the potential for cumulative toxicity from acute doses may not be quantitatively predictable. For repeated-exposure toxicity, the precise profiling of doses may significantly influence toxicity.

1.9.4. *Miscellaneous Factors Influencing the Magnitude of Toxic Responses*

A variety of other factors may affect the nature and exhibition of toxicity, depending on the conditions of the study, for example, housing conditions, handling, volume of dosing, vehicle, etc. Variability in test conditions and procedures may result in significant interlaboratory variability in results of otherwise standard procedures. For chemicals given orally or applied to the skin, toxicity may be modified by the presence of materials in formulations which facilitate or retard the absorption of the chemicals. With respiratory exposure to aerosols, particle size significantly determines the depth of penetration and deposition in the respiratory tract and thus the site and extent of the toxic effects.

1.10. Exposure to Mixtures

In experimental animals most data on the toxic effects of chemicals are collected after exposure to a single chemical; in contrast, human exposure normally occurs to mixtures of chemicals at low doses. Moreover, prior, coincidential, and sucessive exposure of humans to chemicals is likely. Interactions between the toxic effects of different chemicals are difficult to predict, effects of exposure to different chemicals may be independent, additive, potentiating (ethanol and carbon tetrachloride), antagonistic (interference with action of other chemical, e.g., as seen with antidotes administered in case of intoxications), and synergistic. Ethanol exerts a potentiating effect on the hepatotoxicity of carbon tetrachloride. In rats pretreated with ethanol, the hepatotoxic effects of carbon tetrachloride are much more pronounced than in control animals. This potentiation is due to an increased capacity for bioactivation (see Section Storage of Xenobiotics in Organs and Tissues) of carbon tetrachloride in pretreated rats due to increased concentrations of a cytochrome P450 enzyme in the liver [20]. Thus, an important considerations for the assessement of potential toxic effects of mixtures of chemicals are toxicokinetics and toxicodynamic interactions. Toxicokinetic interactions of chemicals may influence absorption, distribution, and biotransformation, both to active and inactive metabolites. Mixtures of solvents often show a competitive inhibition of biotransformation. Usually, one of the components has high affinity for a specific enzyme involved in its biotransformation, whereas another component has only a low affinity for that particular enzyme. Thus, preferential biotransformation of the component with the high affinity occurs. Different outcomes of enzyme inhibition are possible: if the toxic effects of the component whose metabolism is inhibited is dependent on bioactivation, lower rates of bioactivation will result in decreased toxicity; if the toxic effects are independent of biotransformation, the extent of toxicity will increase due to slower rate of excretion. Toxic effects of mixtures may also not be due to a major component, but to trace impurities with high toxicity. For example, many long-term effects seen in animal studies on the toxicity of chlorophenols are believed to be due to 2,3,7,8-Tetrachlorodibenzodioxin, which was present as a minor impurity in the samples of chlorophenols used for these studies.

[Top of Page]

2. Absorption, Distribution, Biotransformation and Elimination of Xenobiotics

2.1. Disposition of Xenobiotics

The induction of systemic toxicity usually results from a complex interaction between absorbed parent chemical and biotransformation products formed in tissues; the distribution of both parent chemical and biotransformation products in body fluids and tissues; their binding and storage characteristics; and their excretion.

The biological effects initiated by a xenobiotic are not related simply to its inherent toxic properties; the initiation, intensity, and duration of response are a function of numerous factors intrinsic to the biological system and the administered dose. Each factor influences the ultimate interaction of the xenobiotic and the active site (Section Factors Influencing Dose–Response). Only when the toxic chemical has reached the specific site and interacted with it can the inherent toxicity be realized. The route a xenobiotic follows from the point of administration or absorption to the site of action usually involves many steps and is termed toxicokinetics. Toxicokinetics influence the concentration of the xenobiotic or its active metabolite at the receptor. In the dose–response concept outlined in Section Dose–Response: a Fundamental Issue in Toxicology, it is generally assumed that the toxic response is proportional to the concentration of the xenobiotic at the receptor. However, the same dose of a chemical administered by different routes may cause different toxic effects. Moreover, the same dose of two different chemicals may result in vastly different concentrations of the chemical or its biotransformation products in a particular target organ. This differential pattern is due to differences in the disposition of a xenobiotic (Fig. 11).

Figure 11. Possible fate of a xenobiotic in the organisms

The disposition of a xenobiotic consists of absorption, distribution, biotransformation, and excretion, which are all interrelated. The complicated interactions between the different processes of distribution are very important determinants of the concentration of a chemical at the receptor and thus of the magnitude of toxic response. They may also be major determinants for organ-specific toxicity.

For example, in the case of absorption of a xenobiotic through the gastrointestinal tract, the chemical proceeds from the intestinal lumen into the epithelial cells. Following intracellular transport, it passes through the basal membrane and lamina propria and enters the blood or lymph capillaries for transport to the site of action or storage. At that site, the xenobiotic is released from the capillaries, into an interstitial area, and finally through various membranes to its site of action, which may be a specific receptor, an enzyme, a membrane, or many other possible sites.

2.2. Absorption

The skin, the lungs, and the cells lining the alimentary tract are major barriers for chemicals present in the environment. Except for caustic chemicals, which act at the site of first contact with the organism, xenobiotics must cross these barriers to exert toxic effects on one or several target organs. The process whereby a xenobiotic moves through these barriers and enters the circulation is termed absorption.

2.2.1. *Membranes*

Because xenobiotics must often pass through membranes on their way to the receptor, it is important to understand membrane characteristics and the factors that permit transfer of foreign compounds. Membranes are initially encountered whether a xenobiotic is absorbed by the dermal, oral, or vapor route. These membranes may be associated with several layers of cells or a single cell. The absorption of a substance from the site of exposure may result from passive diffusion, facilitated diffusion, active transport, or the formation of transport vesicles (pinocytosis and phagocytosis). The process of absorption may be facilitated or retarded by a variety of factors; for example, elevated temperature increases percutaneous absorption by cutaneous vasodilation, and surface-active materials facilitate penetration. Each area of entry for xenobiotics into the organism may have specific peculiarities, but a unifying concept of biology is the basic similarity of all membranes in tissues, cells, and organelles.

All membranes are lipid bilayers with polar head groups (phosphatidylethanolamine, phosphatidylcholine). The polar groups predominate at the outer and inner surfaces of the membrane; the inner space of the membrane consists of perpendicularly arranged fatty acids [21]. The fatty acids do not have a rigid structure and are fluid under physiological conditions; the fluid character of the membrane is largely dominated by the fatty acid composition. The width of a biological membrane is approximately 7–9 nm. Figure 12 illustrates the concept of a biological membrane (fluid-mosaic model).

Figure 12. Simplified model of the structure of a biological membrane

Proteins are intimately associated with the membrane and may be located on the surface or inside the membrane structure, or extend completely through the membrane. These proteins may also form aqueous pores. Hydrophobic forces are responsible for maintaining the structural integrity of both proteins and lipids within the membrane structure. The ratio of lipid to protein in different membranes may vary from 5:1 (e.g,. myelin) to 1:5 (e.g., the inner membrane of mitochondria). Usually, pore diameters in membranes are small and permit only the passage of low molecular mass chemicals. However, some specialized membranes such as those found in the glomeruli of the kidney, which can have pore sizes of up to 4 nm, also permit the passage of compounds with molecular mass greater than 10 000.

The amphipathic nature of the membrane creates a barrier for ionized, highly polar compounds; however, changes in lipid composition, alterations in the shape and size of proteins, and physical features of bonding may cause changes in the permeability of membranes [22].

2.2.2. *Penetration of Membranes by Chemicals*

A chemical can pass through a membrane by two general processes: passive diffusion and active transport. Passive diffusion is described by Fick's law and requires no energy. Active transport processes involve the consumption of cellular energy to translocate the chemical across the membrane. Active transport may also act against a concentration gradient and result in the accumulation of a xenobiotic in a specific organ, cell type or organelle.

Diffusion of Chemicals through Membranes. Many toxic chemicals pass membranes by simple diffusion. Their rates of diffusion depend on their lipid solubility and are often correlated with the partition coefficient (solubility in organic solvents/solubility in water). Lipophilic chemicals may diffuse directly through the lipid domain of the membrane. However, a certain degree of water solubility seems to be required for passage since many poorly lipid soluble chemicals have been shown to penetrate easily. Once initial penetration has occurred, the molecule must necessarily traverse a more polar region to dissociate from the membrane. Compounds with extremely high partition coefficients thus tend to remain in membranes and to accumulate there rather than pass through them. Polar compounds that are insoluble in the nonpolar, fatty-acid-containing inner space of the membrane often cannot penetrate membranes, although some low molecular mass polar chemicals may slowly penetrate through the aqueous pores of the membranes.

The rates of movement of nonpolar xenobiotics through membranes can be predicted based on the assumptions from Fick's law of diffusion. Polar compounds and electrolytes of low molecular mass are believed to behave similarily. A first-order equation appears to be applicable to the majority of xenobiotics. The rate of diffusion of a xenobiotic is related to its concentration gradient across the membrane ($C_1 - C_2$), the surface area available for transfer A, the diameter of the membrane d, and the diffusion constant k. The latter is related to the size and structure of the molecule, the spatial configuration of the molecule, and the degree of ionization and lipid solubility of the xenobiotic.

$$\text{Rate of diffusion} = k\frac{A(C_1 - C_2)}{d}$$

As the xenobiotic is rapidly removed after absorption, C_2 can usually be ignored. and a log/linear plot of the amount of unpenetrated chemicals present over time should be linear. When relatively comparable methods have been used, calculation of the half-time of penetration $t_{1/2}$, is useful. The rate constant of penetration k is derived from

$$k = \frac{0.693}{t_{1/2}}$$

When the half-time of penetration after oral and dermal administration of several environmental contaminants were compared, rates were found to vary considerably. Clearly, rates of penetration by different routes in mammals show little or no correlation.

Ionization becomes particularly important when xenobiotics are introduced into the gastrointestinal tract, where a variety of pH conditions are manifest (see Section Gastrointestinal Absorption). Although many drugs are acids and bases and thus potentially ionizable form, most xenobiotics are neither acids nor bases and thus are unaffected by pH. The amount of a xenobiotic in the ionized or unionized form depends upon the pK_a of the xenobiotic and the pH of the medium. When the pH of a solution is equal to the pK_a of the dissolved compound, 50% of the acid or base exists in the ionized and 50% in the unionized form. The degree of ionization at a specific pH is given by the Henderson–Hasselbalch equation:

$$pK_a - \text{pH} = \log\frac{[\text{nonionized}]}{[\text{ionized}]}$$

$$pK_a - \text{pH} = \log\frac{[\text{ionized}]}{[\text{nonionized}]}$$

Since the unionized, lipid-soluble form of a weak acid or base may penetrate membranes, weak organic acids diffuse most readily in an acidic environment, and organic bases in a basic environment. There is some degree of penetration even when xenobiotics are not in the most lipid-soluble form, and a small amount of absorption can produce serious effects if a compound is very toxic.

2.2.3. *Mechanisms of Transport of Xenobiotics through Membranes*

Filtration. Passage of a solution across a porous membrane results in the retention of solutes larger than the pores. This process is termed filtration. For example, filtration of solutes occurs in the kidney glomeruli, which have large pores and retain molecules with molecular masses greater than 10 000. Elsewhere in the body, filtration by pores may only result in the passage of relatively small molecules (molecular mass ca. 100), and most larger molecules are excluded. Thus, uptake of xenobiotics through these pores is only a minor mechanism of penetration.

Special Transport Mechanisms. Special transport processes include active transport, facilitated transport, and endocytosis (Table 8). Often, the movement of chemicals across membranes is not due to simple diffusion or filtration. Even some very large or very polar molecules may readily pass through membranes.

Table 8. Special transport processes involved in the passage of xenobiotics through biological membranes

Type of transport	Carrier molecule required	Examples of substrates	Energy required	Against concentration gradient
Active transport	yes	organic acids in the kidney	yes	yes
Facilitated transport	yes	glucose	yes	no
Endocytosis	no	proteins	yes	?

Active transport systems have frequently been implicated in these phenomena. *Active transport* may be effected by systems that help transport endogenous compounds across membranes. Such processes require energy and transport xenobiotics against electrochemical or concentration gradients. Active transport systems are saturable processes and exhibit a maximum rate of transport; they are usually specific for certain structural features of chemicals. A carrier molecule (likely a protein) associates with the chemical outside the cell, translocates it across the membrane for ultimate release inside the cell. This is particularly important for compounds that lack sufficient lipid solubility to move rapidly through the membrane by simple diffusion. Active transport plays a major role in the excretion of xenobiotics from the body, and major excretory organs such as the liver or the kidney have several transport systems which may accept organic acids, organic bases, or even metal ions as substrates.

In contrast to other special transport processes, some carrier-mediated processes do not require energy and are unable to move chemicals against a concentration gradient. These processes are termed *facilitated transport*. Facilitated transport is particulary beneficial for compounds which lack sufficient lipid solubility for rapid diffusion through the membrane. Facilitated transport is more rapid than simple diffusion up to the point at which concentrations on both sides of the membranes are equal. For example, the transport of glucose through a variety of membranes occurs by facilitated transport. The mechanisms by which facilitated transport occurs are not well understood.

Pinocytosis (liquids) and *phagocytosis* (solids) are specialized processes in which the cell membrane invaginates or flows around a xenobiotic, usually present in particulate form, and thus enables transfer across a membrane. Although of importance once the xenobiotic has gained entry into the organism, this mechanism does not appear to be of importance in the initial absorption of a xenobiotic.

2.2.4. *Absorption*

Absorption is the process whereby xenobiotics cross body membranes and are translocated to the blood stream. The primary sites of absorption of environmental contaminants are the gastrointestinal tract (gastrointestinal absorption), the skin (dermal absorption), and the lung (respiratory absorption). Absorption of chemicals may also occur from other sites such as muscle, the subcutis, or the peritoneum after administration by special routes. In clinical medicine, many drugs are injected directly into the bloodstream to circumvent the problems of absorption posed by the peculiarities of the different routes.

2.2.4.1. *Dermal Absorption*

Human skin can come into contact with many potentially toxic chemicals. Skin is relatively impermeable to aqueous solutions and most xenobiotics present as ions. Therefore, it is a relatively good barrier separating the human body from the environment. However, skin is permeable in varying degrees to a large number of xenobiotics, and some chemicals may be absorbed through the skin in sufficient amounts to cause a toxic response [23]. A striking example of the significance of absorption through the skin is the large number of agricultural workers who have experienced acute poisoning from exposure to parathion (dermal $LD_{50} \approx 20$ mg/kg) during application or from exposure to vegetation previously treated with this pesticide.

The human skin is a complex, multilayered tissue with approximately 18 000 cm^2 of surface in an average human male. Chemicals to be absorbed must pass through several cell layers before entering the small blood and lymph capillaries in the dermis. Transport in blood and lymph then distributes absorbed chemicals in the body. The human skin consists of three distinct layers (Fig. 13) and a number of associated appendages (sweat and sebaceous glands, hair follicles).

Figure 13. Cross section of human skin

a) Stratum corneum; b) Sebaceous gland; c) Sweat gland; d) Hair follicle; e) Fat; f) Muscle

The *epidermis* is a multilayered tissue varying in thickness from 0.15 (eyelids) to 0.8 mm (palms). This tissue appears to be the greatest deterrent to the absorption of xenobiotics. The epithelial tissues of the skin develop and grow divergently from other tissues. Proliferative layers of the basal cells (stratum germinativum) differentiate and gradually replace cells above them as surface cells deteriorate and are sloughed from the epidermis. Cells in this layer produce fibrous, insoluble keratin that fills the cells, and a sulfur-rich amorphous protein that comprises the cell matrix and thickened cell membrane. This cell layer, the stratum corneum, provides the primary barrier to the penetration of foreign compounds. It consists of several layers of flattened, stratified, highly keratinized cells. These cells are approximately 25–40 µm wide and have lost their nuclei. Although highly water retarding, the dead, keratinized cells of the stratum corneum are highly water absorbent (hydrophilic), a property that keeps the skin supple and soft. A natural oil covering the skin, the sebum, appears to maintain the water-holding capacity of the epidermis but has no appreciable role in retarding the penetration of xenobiotics. The rate-determining barrier in the chemical absorption of xenobiotics is the stratum corneum.

The *dermis* and *subcutaneous tissue* offer little resistance to penetration, and once a substance has penetrated the epidermis these tissues are rapidly traversed. The dermis is a highly vascular area that provides ready access to blood and lymph for distribution once the epithelial barrier has been passed. The blood supply in the dermis is subjected to complex, interacting neural and humoral influences whose temperature-regulating function can have an effect on distribution by altering blood supply to this area. Therefore, the extent of absorption of a chemical through the skin may be influenced by temperature, and relative humidity [24].

The *skin appendages* are found in the dermis and extend through the epidermis. The primary appendages are the sweat glands (epicrine and apocrine), hair, and sebaceous glands. These structures extend to the outer surface and therefore may play a role in the penetration of xenobiotics; however, since they represent only 0.1 to 1% of the total surface of the skin, their contribution to overall dermal absorption is usually minor.

Percutaneous absorption can occur by several routes, but the majority of unionized, lipid-soluble xenobiotics appear to move by passive diffusion directly through the cells of the stratum corneum. Important arguments for the importance of transepidermal absorption are that epidermal damage or removal of the stratum corneum increases permeability, the epidermal penetration rate equals whole-skin penetration, epidermal penetration is markedly slower than dermal, and the epidermal surface area is 100–1000 times the surface area of the skin appendages. Very small and/or polar molecules appear to have more favorable penetration through appendages or other diffusion shunts, but only a small fraction of toxic xenobiotics are chemicals of this type. Polar substances, in addition to movement through shunts, may diffuse through the outer surface of the protein filaments of the hydrated stratum corneum, while nonpolar molecules dissolve in and diffuse through the nonaqueous lipid matrix between the protein filaments.

Human stratum corneum displays significant differences in structure from one region of the body to the other, which affect the rate of absorption. Penetration at certain body regions thus varies according to the polarity and size of the molecule, but it is generally accepted that for most unionized xenobiotics the rate of penetration is in the following order: scrotal > forehead > axilla = scalp > back = abdomen > palm and plantar. The palm and plantar regions are highly diffuse, but their much greater thickness (100–400 times that of other regions) introduces an overall lag time in diffusion.

The condition of the skin greatly influences the absorption of xenobiotics. Damage to or removal of the stratum corneum cause a dramatic increase in the permeability of the epidermis for xenobiotics. Caustic and corrosive chemicals such as acids or alkali or burns will greatly enhance dermal absorption and thus influence the toxicity of a xenobiotic applied to the skin. Soaps and detergents are among the damaging substances routinely applied to skin. Whereas organic solvents must be applied in high concentrations to damage skin, 1% aqueous solutions of detergents increase the rate of penetration of solutes through human epidermis dramatically. Alteration of the stratum corneum by organic solvents may also be the cause of increased penetration.

Organic solvents can be divided into damaging and nondamaging categories. Damaging solvents include methanol, acetone, diethyl ether, hexane, and some solvent mixtures. These solvents and mixtures can extract lipids and proteolipids from tissues and are thus expected to alter permeability. Although the mechanical strength of the stratum corneum is unaltered, delipidization produces a more porous, nonselective surface. Solvents such as higher alcohols, esters, and olive oil do not appear to damage skin appreciably. On the contrary, the penetration rate of solutes dissolved in them is often reduced. Surprisingly, lipid-soluble xenobiotics may be markedly resistant to washing, even a short time after application. For example, 15 min after application, a substantial portion of parathion cannot be removed from

contaminated skin by soap and water.

When comparisons across species are made, human skin appears to be more impermeable, or at least as impermeable, as the skin of the cat, dog, rat, mouse, or guinea pig. The skin of pigs and guinea pigs in particular serves as a useful approximation to human skin, but only after a comparison has been made for each specific chemical.

Temperature, surface area of applied dose, simultaneous application of another xenobiotic, relative humidity, occlusion, age, and hyperthermia are among a number of chemical, physical, and physiological factors that may alter skin penetration.

2.2.4.2. *Gastrointestinal Absorption*

The oral route of entry into the body is specially important for accidental or purposeful (suicide) ingestion of poisonous materials. Food additives, food toxins, environmental xenobiotics accumulated in the food chain, and airborne particles excluded from passage to to alveoli are also introduced into the digestive system. The penetration of orally administered xenobiotics is primarily confined to the stomach and intestine [25].

The gastrointestinal tract may be viewed as a tube traversing the body. It consists of the mouth, esophagus, stomach, small and large intestine, colon, and rectum (Fig. 14). The digestive tract is lined by a single layer of columnar cells, usually protected by mucus, which do not present a barrier to penetration. The circulatory system is closely associated with the intestinal tract (30–50 µm from membrane to vasculature), and once xenobiotics have crossed the epithelium of the intestinal tract, entry into capillaries is rapid. Venous blood flow from the stomach and intestine rapidly removes absorbed xenobiotics and introduces them into the hepatic portal vein, which transports them to the liver.

Figure 14. A) Intestinal tract in humans; B) Anatomy of the intestinal wall, the major site of absorption of xenobiotics

The lining of the small intestine is highly folded and has a special surface structure (brush-border membrane) to give a large surface available for the efficient uptake of nutrients.

a) Esophagus (4 – 7.2); b) Stomach (1.0 – 3.0); c) Duodenum (4.8 – 8.2); d) Pancreas; e) Colon (7.9 – 8.0); f) Jejunum (7.6); g) Ileum (7.6); h) Rectum (7.8); i) Brush-border membrane

Numbers in brackets represent pH in different parts of the intestinal tract.

Absorption of chemicals may take place along the entire gastrointestinal tract, but most xenobiotics are absorbed in the stomach and the small intestine. A major factor favoring absorption in the intestine is the presence of microvilli that increase the surface area to an estimated 100 m^2 in the small intestine (see Fig. 14) Because the intestinal area thus offers maximal opportunity for absorption, it is generally accepted that absorption of xenobiotics is greatest in this area of the gastrointestinal tract. Although the gastrointestinal tract has some special transport processes for the absorption of nutrients and electrolytes, most xenobiotics seem to enter the body from the gastrointestinal tract by simple diffusion. Exeptions are some heavy metals such as thallium and lead, which mimic the essential metals iron and calcium, respectively. They are thus absorbed by active transport systems developed for the uptake of these nutrients.

The gastrointestinal tract has areas of highly variable pH, which can markedly change the permeability characteristics of ionic compounds. For example, passive diffusion is greatly limited except for unionized, lipid-soluble chemicals. Although variable according to secretory activity, the pH of the stomach is ca. 1–3 and that of the intestine ca. 7. The measured pH of the intestinal contents may not be the same as the pH of the epithelium at the site of absorption, and this explains the entrance of compounds whose p*K*a would suggest less favored absorption. The variations in pH in the different sections of the intestinal tract may influence the absorption of acids and bases. Since most xenobiotics are absorbed by diffusion, only the unionized, membrane-permeable form may be absorbed. Weak organic acids are mainly present in the unionized, lipid-soluble form in the stomach, and predominantly in the ionized form in the intestine. Therefore, organic acids are expected to be more readily absorbed from the stomach than from the intestine. In contrast, weak organic bases are ionized in the stomach but present in the lipid-soluble form (unionized) in the intestine. Absorption of such compounds should therefore predominantly occur in the intestine rather than in the stomach.

However, other factors determining the rate of membrane penetration such as surface area available for diffusion, blood flow (influencing concentration gradients), and the law of mass action also influence the site of absorption of acids or bases from the gastrointestinal tract. For example, although only 1% of benzoic acid is present in the lipid-soluble, unionized form in the small intestine, the large surface area and the rapid removal of absorbed benzoic acid with the blood result in its efficient absorption from the small intestine.

Other factors contribute to gastrointestinal absorption Clearly a xenobiotic must be dissolved before absorption can take place. Particle size, organic solvents, emulsifiers, and rate of dissolution thus also effect absorption. In addition, the presence of microorganisms and hydrolysis-promoting pH offer opportunities for the biotransformation of many xenobiotics. Other factors affecting gastrointestinal absorption include binding to gut contents, intestinal motility, rate of emptying, temperature of food, effects of dietary constituents, health status of the individual, and gastrointestinal secretion.

2.2.4.3. *Absorption of Xenobiotics by the Respiratory System*

The respiratory system is an organ in direct contact with environmental air as an unavoidable part of living. A number of xenobiotics exist in gaseous (carbon monoxide, nitric oxides), vapor (benzene, carbon tetrachloride), and aerosol (lead from automobile exhaust, silica, asbestos) forms and are potential candidates for entry via the respiratory system. Indeed, the most important cause of death from acute intoxication (carbon monoxide) and the most frequent occupational disease (silicosis) are caused by the absorption or deposition of airborne xenobiotics in the lung.

The respiratory tract consists of three major regions: the nasopharyngeal, the tracheobronchial, and the pulmonary (Fig. 15). The nasopharynx begins in the mouth and extents down to the level of the larynx. The trachea, bronchii, and bronchioli serve as conducting airways between the nasopharynx and the alveoli, the site of gas exchange between the inhaled air and the blood. The human respiratory system is a complex organ containing over 40 different cell types. These cell types contribute to the pulmonary architecture and function over various zones of the lung, although to some extent, individual cell types can be found in several zones. The tracheobronchial system comprises airways lined with bronchial epithelium with associated submucosal glands and several different tissues with specific function and the lung vasculature.

Figure 15. Anatomy of the human respiratory system

a) Trachea; b) Bronchii; c) Bronchioli; d) Alveoli; e) Capillary; f) Erythrocyte

The absorption of xenobiotics by the respiratory route is favored by the short path of diffusion, large surface area (50–100 m^2), and large concentration gradients. At the alveoli (site of gas exchange), the membranes are very thin (1–2 µm) and are intimately associated with the vascular system. This enables rapid exchange of gases (ca. 5 ms for CO_2 and ca. 200 ms for O_2). A thin film of fluid lining the alveolar walls aids in the initial absorption of xenobiotics from the alveolar air. Simple diffusion accounts for the somewhat complex series of events in the lung regarding gas absorption. The sequences of respiration, which involve several interrelated air volumes, define both the capacity of the lung and factors important to particle deposition and retention. Among the elements important in total lung capacity is the residual volume, that is, the amount of air retained by the lung despite maximal expiratory effort. Largely due to slow release from this volume, gaseous xenobiotics in the expired air are not cleared immediately, and many expirations may be necessary to rid the air in the lung of residual xenobiotic. The rate of entry of vapor-phase xenobiotics is controlled by the alveolar ventilation rate, and a xenobiotic present in alveolar air may come into contact with the alveoli in an interrupted fashion about 20 times per minute. The diffusion coefficient of the gas in the fluids of pulmonary membranes is another important consideration, but doses are more appropriately discussed in terms of the partial pressure of the xenobiotic in the inspired air. On inhalation of a constant tension of a gaseous xenobiotic, arterial plasma tension of the gas approaches the tension of gas in the expired air. The rate of entry is then determined by blood solubility of the xenobiotic and blood flow. For a high blood/gas partition coefficient, a larger amount must be dissolved in the blood to raise the partial pressure. Chemicals with a high blood/gas partition coefficient require a longer period to approach the same tension in the blood as in inspired air than less soluble gases.

Aerosols and Particulates. The entry of aerosols and particulates is affected by a number of factors. A coal miner inhales ca. 6000 g of coal dust particles during his occupational lifetime, and only ca. 100 g are found postmortem; therefore, effective protective mechanisms are operative. The parameters of air velocity and directional changes in air flow favor impaction of particles in the upper respiratory systems. Particle characteristics such as size, chemistry of the inhaled material,

sedimentation and electrical charge are important to retention, absorption, or expulsion of airborne particles. In addition to the other aforementioned lung characteristics, a mucous blanket propelled by ciliary action clears the respiratory tract of particles by directing them to the gastrointestinal system (via the glottis) or to the mouth for expectoration. This system is responsible for 80% of lung particulate clearance. The deposition of various particle sizes in different respiratory regions is summarized in Figure 16, which shows that particle size is important for disposition and particles larger than 2 µm do not reach the alveoli [26].

Figure 16. Effect of size on the disposition and sedimentation of particulates in the respiratory tract

The site of particle sedimentation is determined largely by particle size; only very fine particles are deposited in the alveoli; larger particles do not reach the lung but are deposited in the nasopharynx.

The direct penetration of airborne xenobiotics at alveolar surfaces or in the upper respiratory tract is not the only action of toxicological importance. Both vapors and particulates can accumulate in upper respiratory passages to produce irritant effects. Irritant gases may be deposited in the respiratory tract depending on their water solubility and may cause localized damage characterized by edema, swelling, mucus production, and increased d vascular permeability. If major airways are obstructed by these processes or important anatomical structures of the respiratory tract like the alveoli are damaged, life-threatening or deadly intoxications may be caused by the inhalation of irritant gases.

Despite the effectiveness of ciliary movement and phagocytosis, the cumulative effects of silica, asbestos, or coal dust ultimately cause chronic fibrosis even though direct absorption is of minor importance. Thus, phagocytosis prevents acute damage but may contribute to chronic toxicity. There is little evidence for active transport in the respiratory system, although pinocytosis may be of importance for penetration. The lung is an area of extensive metabolic activity; enzymes present in the lung may catalyze both activation and detoxication of xenobiotics (see Section Storage of Xenobiotics in Organs and Tissues).

2.3. Distribution of Xenobiotics by Body Fluids

After entering the blood by absorption or by intravenous administration, xenobiotics are available for distribution throughout the body. The initial rate of distribution to organs and tissues is determined by the blood flow to that organ and the rate of diffusion of the chemical into the specific organ or tissue. Uptake of xenobiotics into organs or tissues may occur by either passive diffusion or by special transport processes. Within tissues binding, storage, and/or biotransformation may occur. After reaching equilibrium, the distribution of a chemical among organs and tissues is largely determined by affinity; blood flow determines distribution only during the initial phase shortly after uptake.

Body fluids are distributed between three distinct compartments: vascular water, interstitial water and intracellular water. Plasma water and interstitial water are extracellular water. Plasma water plays an important role in the distribution of xenobiotics. Human plasma accounts for about 4% of the total body weight and 53% of the total volume of blood. By comparison, the interstitial tissue fluids account for 13% of body weight, and intracellular fluids account for 41%. The concentration of a xenobiotic in blood following exposure will depend largely on its apparent volume of distribution. If the xenobiotic is distributed only in the plasma, a high concentration will be achieved within the vascular tissue. In contrast, the concentration will be markedly lower if the same quantity of xenobiotic were distributed in a larger pool including the interstitial water and/or intracellular water.

Among the factors that affect distribution, apart from binding to blood macromolecules, are the route of administration, rate of biotransformation, polarity of the parent xenobiotic or biotransformation products, and rate of excretion by the liver or kidneys. Gastrointestinal absorption and intraperitoneal administration provide for immediate passage of a compound to the liver, whereas dermal or respiratory routes involve at least one passage through the systemic circulation prior to reaching the liver. The metabolism of most xenobiotics results in products that are more polar and thus more readily excreted than the parent molecules. Therefore, the rate of metabolism is a critical determinant in the distribution of a compound, since compounds that are readily metabolized are usually readily excreted, and thus are proportionally less prone to accumulate in certain tissues. The same principle applies to polarity, since very polar xenobiotics will be readily excreted. Chemicals may circulate either free or bound to plasma protein or blood cells; the degree of binding and factors influencing the equilibrium with the free form may influence availability for biotransformation, storage, and/or excretion [27].

Patterns of xenobiotic distribution reflect certain physiological properties of the organism and the physicochemical properties of the xenobiotics. An initial phase of distribution may be distinguished that reflects cardiac output and blood flow to organs. Heart, liver, kidney, brain, and other well-perfused organ- receive most of a lipophilic xenobiotic within the first few minutes after absorption. Delivery to the smooth muscles, most viscera, and skin is slower, and the time to reach a steady-state concentration of a xenobiotic in these organs may be several hours. A second phase of xenobiotic distribution may therefore be distinguished; it is limited by blood flow to an organ or tissue and involves a far larger fraction of body mass than the first phase of distribution (Fig. 17).

Figure 17. Uptake and redistribution with blood of lipophilic xenobiotics

Lipophilic xenobiotics in the blood are first distributed to well-perfused organs (A); after some time, they are redistributed to organs with lower blood flow representing a larger fraction of the body weight (B, C)

Only a limited number of xenobiotics have sufficient solubility in blood to account for simple dissolution as a route of distribution; the distribution of many xenobiotics occurs in association with plasma proteins. The binding of drugs to plasma proteins is of key importance in transport. Many organic and inorganic compounds of low molecular mass appear to bind to lipoproteins, albumins, and other proteins in plasma and are transported as protein conjugates. This binding is reversible. Cellular components may also be responsible for transport of xenobiotics, but such transport is rarely a major route. The transport of xenobiotics by lymph is usually quantitatively of little importance since the intestinal blood flow is 500–700 times greater than the intestinal lymph flow.

A large number of studies on binding of drugs by plasma protein have demonstrated that binding to serum albumin is particularly important for these chemicals. Only few studies on the reversible binding of toxic xenobiotics have been performed, but available evidence suggests a significant role of lipoproteins in plasma. These plasma proteins may bind xenobiotics as well as some physiological constituents of the body. Examples for plasma proteins which may bind xenobiotics are albumin, α- and β-lipoproteins, and metal-binding proteins such as transferrin. Lipoproteins are important for the transport of lipid-soluble endogenous chemicals such as vitamins, steroid hormones, and cholesterol, but they may also bind lipophilic xenobiotics. If a xenobiotic is bound to a protein, it is immobilized remote from the site of action. The extent of binding to plasma proteins varies considerably among xenobiotics. While some are not at all bound, for others more than 90% of administered dose may be bound to plasma proteins. These ligand–protein interactions are reversible and provide a remarkably efficient means for transport of xenobiotics to various tissues.The xenobiotic–protein interaction may be simply described according to the law of mass action as:

$$[T]_F + [\text{free sites}] \underset{k_2}{\overset{k_1}{\rightleftharpoons}} [T]_B$$

where $[T]_F$ and $[T]_B$ are the concentrations of free and bound xenobiotic molecules, respectively, and k_1 and k_2 are the rate constants for association and dissociation; k_2, which governs the rate of binding to the protein, dictates the rate of xenobiotic release at a site of action or storage. The ratio k_1/k_2 is identical with the dissociation constant K_{diss}. Among a group of binding sites on proteins, those with the smallest K_{diss} for a given xenobiotic will bind it most tightly.

In contrast to the covalent binding to proteins seen with many xenobiotics or their electrophilic metabolites (see Section Interaction of Reactive Intermediates with Cellular Macromolecules), the interaction of xenobiotics with plasma proteins is most often noncovalent and reversible. Noncovalent binding is of primary importance with respect to distribution because of the opportunities to dissociate after transport. Binding of xenobiotics to plasma proteins may be due to several types of interactions which are summarized in the following.

Ionic Binding. Electrostatic attraction occurs between two oppositely charged ions. The degree of binding varies with the chemical nature of each compound and the net charge. Dissociation of ionic bonds usually occurs readily, but some transition metals exhibit high association constants (low K_{diss} values), and exchange is slow. Ionic interactions may also contribute to binding of alkaloids with ionizable nitrogen groups and other ionizable xenobiotics.

Hydrogen Bonding. Generally, only the most electronegative atoms form stable hydrogen bonds. Protein side chains containing hydroxyl, amino, carboxyl, imidazole, and carbamyl groups may form hydrogen bonds, as can the nitrogen and oxygen atoms of peptide bonds. Hydrogen bonding plays an important role in the

structural configuration of proteins and nucleic acids.

Van der Waals forces are very weak interactions between the nucleus of one atom and the electrons of another atom, i.e., between dipoles and induced dipoles. The attractive forces are based on slight distortions induced in the electron clouds surrounding each nucleus as two atoms come close together. The binding force is critically dependent upon the proximity of interacting atoms and diminishes rapidly with distance. However, when these forces are summed over a large number of interacting atoms that "fit" together spatially, they can play a significant role in determining specificity of xenobiotic–protein interactions.

Hydrophobic Interactions. When two nonpolar groups come together they exclude the water between them, and this mutual repulsion of water results in a hydrophobic interaction. In the aggregate they represent the least possible disruption of interactions among polar water molecules and thus can lead to stable complexes. Some consider this a special case of van der Waals forces. The minimization of thermodynamically unfavorable contact of a polar group with water molecules provides the major stabilizing effect in hydrophobic interactions.

Consequences of the binding to plasma proteins are reduced availability of the free xenobiotic in the cells and a delayed excretion. The xenobiotic bound to plasma protein cannot cross capillary walls due to its high molecular mass. The fraction of dose bound is thus not available for delivery to the extravascular space or for filtration by the kidney. It is generally accepted that the fraction of xenobiotic that is bound may not exert toxic effects; however, many xenobiotics and endogenous compounds appear to compete for the same binding site, and thus one compound may alter the unbound fraction of another by displacement, thereby potentially increasing toxic effects. Plasma proteins that can bind endogenous chemicals and xenobiotics are listed below, together with examples of bonded xenobiotics:

α-Lipoproteins	vitamins A, K, D
	steroid hormones
	dieldrin
Albumin	salicylate
	tetracyclines
	phenols
	vitamin C

Binding of xenobiotics to plasma proteins is mostly reversible; the bound xenobiotic is in equilibrium with free xenobiotic, and thus binding usually slows excretion or delivery to cellular sites of action. Toxicological consequences of the reversible binding of a xenobiotic to plasma proteins may arise after saturation of the binding capacities of plasma proteins and by displacement of the bound xenobiotic by another chemical with higher affinity, which increases the free fraction of the formerly bound xenobiotic. This will result in an increased equilibrium concentration of the xenobiotic in plasma and in the target organ, with potentially harmful consequences.

2.4. Storage of Xenobiotics in Organs and Tissues

Absorbed xenobiotics may be concentrated in specific organs or tissues. The concentration of a xenobiotic in a specific tissue may cause toxic effects to that particular tissue; some xenobiotics actually attain their highest concentration at the site of toxic action. However, other xenobiotics may be concentrated in tissues without harmful consequences. Some tissues have a high capacity to accommodate certain xenobiotics and may release them only slowly. The compartment or tissue in which a chemical is concentrated can also be considered as a storage depot for this xenobiotic. If a chemical is stored in a depot and thus removed from the site of action (e.g., polychlorinated biphenyls in fat or lead in bone), no immediate manifestation of toxicity may be observed, even though a potential for adverse effects exists. For example, lead stored in bone does not cause a toxic response but has the potential for mobilization and thus for migration into soft tissues; toxic effects may appear after mobilization. As the xenobiotic in storage depots is in equilibrium with the free xenobiotic in plasma, mobilization is constant, and exposure of the target organ to low concentrations of the xenobiotic is constant. Some storage depots for specific chemicals follow:

Lead	bone
Fluoride	bone, teeth
Cadmium	kidney
Iron	transferrin (a blood protein)
Polychlorinated pesticides such as DDT	fat
Arsenic	skin

Liver, kidney, fat, bone, and plasma proteins may serve as storage depots for absorbed xenobiotics. Both liver and kidney have a high capacity to store xenobiotics and are major storage sites for a multitude of chemicals. Accumulation of circulating xenobiotics form the blood by active transport systems and binding to certain tissue constituents are major mechanisms involved in the renal and hepatic storage.

Several thiol-rich proteins present in liver and kidney have a high affinity for xenobiotics [28]. The binding protein ligandin, which as a glutathione *S*-transferase also has enzymatic activity (Section Glutathione Conjugation of Xenobiotics and Mercapturic Acid Excretion) and thus participates in xenobiotic biotransformation, binds organic acids, some azo dyes, and corticosteroids. Metallothionein, a cysteine-rich protein present in liver and kidney, serves as a binding and storage protein for metals such as cadmium and zinc. Its biosynthesis increases after exposure to metals,and this may result in storage of a considerable percentage of cumulative metal dose as metalothionein complex in liver and kidney.

Highly lipophilic chemicals rapidly penetrate membranes and are thus efficiently taken up by tissues. Lipophilic substances that are inefficiently biotransformed accumulate in the most lipophilic environment in the organism, fat. Most xenobiotics seem to accumulate by physical dissolution in neutral fats, which may constitute between 20 and 50% of the body weight in human males. Large amounts of lipophilic xenobiotics may therefore be present in fat; for xenobiotics that do not undergo biotransformation (e.g., 2,3,7,8-tetrachlorodibenzodioxin), determination of the concentration in body fat is a good measure for exposure.

Usually, xenobiotics stored in fat also do not induce toxic responses, since the xenobiotic is not readily available at the target site. However, during rapid mobilization of fat during disease or starvation, a sudden increase in the plasma concentration, and thus toxic effects in target organs, may occur. For example, signs of organochlorine pesticide intoxication have been observed after starvation in animals pretreated with persistent organochlorine pesticides.

Some xenobiotics have a high affinity for bone and may accumulate in the bone matrix. For example, 90% of the lead and a major part of the strontium present in the body after chronic exposure are stored in the skeleton [29]. Lead and strontium accumulate in bone due to their similarity with calcium; inorganic fluoride, which is also a "bone-seeker", accumulates in bone due to similarities in size and charge to the hydroxyl ion. The storage of xenobiotics in bone may or may not be responsible for toxic effects. Lead stored in the skeleton is not toxic to bone, but both stored fluoride and stored strontium cause toxic effects to bone (fluorosis, osteosarcoma). Xenobiotics stored in bone are also in equilibrium with the unbound xenobiotic circulating in plasma and may thus be released.

Certain plasma proteins have a high affinity for xenobiotics, binding of a chemical to plasma proteins may constitute a both transport form and a storage form. Globulins such as transferrin (involved in iron transport) and ceruloplasmin (copper) and α- and β-lipoproteins (lipophilic xenobiotics and endogenous chemicals) may be involved in binding.

Storage in tissue may greatly alter the rate of excretion of a xenobiotic. Only xenobiotics present in plasma are available for distribution, biotransformation, and excretion. However, excretion or biotransformation alters the plasma concentration of the xenobiotic, and some of the stored chemical is released into plasma from the site of storage. Owing to this mechanism, the rate of excretion of a xenobiotic stored in tissues can be very low.

2.5. Biotransformation

Most xenobiotics entering the body are lipophilic. This property enables them to penetrate lipid membranes, to be transported by lipoproteins in the blood, and to be rapidly absorbed by the target organ. However, the efficient excretory mechanisms of the organism require solubility of the xenobiotic in aqueous media and thus a certain degree of hydrophilicity is required for efficient excretion. Lipophilic substances can only be excreted efficiently by exhalation, but this is restricted to volatile xenobiotics. In the absence of efficient means for excretion of nonvolatile chemicals, constant exposure or even intermittent single exposures to a lipophilic chemical could result in accumulation of the xenobiotic in the organism.

Therefore, animal organisms have developed a number of biochemical processes that convert lipophilic chemicals to hydrophilic chemicals and thus assist in their excretion. These enzymatic processes are termed biotransformation, and the enzymes catalyzing biotransformation reactions are referred to as biotransformationenzymes. The biotransformation enzymes differ from most other enzymes by having a broad substrate specifity and by catalyzing reactions at

comparatively low rates. The low rates of biotransformation reactions are often compensated by high concentrations of biotransformation enzymes. For example, ca. 5 wt% of the protein in rat liver consist of cytochromes P450, which are major biotransformation enzymes.

The broad specifity of the biotransformation enzymes likely has evolutionary reasons. Biotransformation enzymes have evolved to facilitate the excretion of lipophilic chemicals present in the diet of animals. The broad substrate specificity helped to adjust to new dietary constituents and thus led to evolutionary advantages.

Biotransformation is generally the sum of several processes by which the structure of a chemical is changed during passage through the organism. The metabolites formed from the parent chemical are usually more water soluble; the increased water solubility reduces the ability of the metabolites to partition into membranes, restricts renal and intestinal reabsorption, and thus facilitates excretion with urine or bile.

2.5.1. *Phase-I and Phase-II Reactions*

Xenobiotic metabolism is catalyzed by a number of different enzymes. For solely operational purposes, the biotransformation enzymes are separated into two phases. In phase-I reactions, which involve oxidation, reduction, and hydrolysis, a polar group is added to the xenobiotic or is exposed by the biotransformation enzymes. Phase-II reactions are biosynthetic and link the metabolite formed by phase-I reactions to a polar endogenous molecule to produce a conjugate. Various endogenous molecules with high polarity and are utilized for conjugation; the resulting conjugates are often ionized at physiological pH and thus highly water soluble. Moreover, the moieties used for conjugation are often recognized by specific active transport processes, which assist in their translocation across plasma membranes and thus further enhance the rate of excretion.

The fate of a particular chemical and the participation of the various phase-I and phase-II biotransformation enzymes is determined by its chemical structure; biotransformation is usually complex and often integrated. Many chemicals bearing functional groups undergo conjugation without prior phase-I biotransformation, whereas others are oxidized or reduced prior to conjugation. However, chemicals lacking functional groups may also undergo phase-II biotransformations without being subjected to a prior phase-I reaction (examples are 1,2-dibromoethane and perchloroethene; see Section Phase-I Enzymes and their Reactions).

2.5.2. *Localization of the Biotransformation Enzymes*

The biotransformation enzymes are localized mainly in the liver. A significant fraction of the blood from the splanchnic area, which also contains xenobiotics absorbed from the intestine, enters the liver. Therefore, the liver has developed the capacity to enzymatically modify most of these chemicals before storage, release, or excretion. However, most other tissues also have the capacity to catalyse biotransformation reactions; indeed, most tissues tested have shown the presence of enzymes which can catalyze biotransformation reactions. The contribution of extrahepatic organs to the biotransformation of a chemical depends on many factors, including chemical structure, dose, and route of administration. However, biotransformation of a chemical within an extrahepatic tissue may have toxic effects on this specific tissue and may thus have important toxicological consequences.

Inside cells, phase-I enzymes are mainly present in the endoplasmatic reticulum, a myriad of lipoprotein membranes extending from the mitochondria and the nucleus to the plasma membranes of the cell. When an organ is homogenized, the endoplasmatic reticulum is broken and membrane fragments are sealed of to form microvesicles. These microvesicles can be sedimented by differential centrifugation, and the materials thus obtained is known as a microsomes. They are highly enriched in vesicles from the endoplasmatic reticulum and retain active biotransformation enzymes. Microsomes are often used to study the enzymatic biotransformation of xenobiotics in vitro.

The presence of phase-I enzymes within membranes has important implications, since lipophilic chemicals will preferentially distribute into lipid membranes; thus, high concentrations of lipophilic xenobiotics are present at this site of biotransformation. In contrast to phase-I enzymes, phase-II enzymes are often soluble, non-membrane-associated, and present in the cytoplasm of the cell. They are found in the supernatant (cytosol) obtained by ultracentrifugation of homogenized tissues. The subcellular localizations of enzymes responsible for biotransformation afollow:

Phase-I enzymes	
–Cytochrome P450	microsomal
–Flavin-dependent mono-oxygenase	microsomal
–Prostaglandin synthase	microsomal
–Epoxide hydrolase	microsomal/cytosolic
Phase-II enzymes	
–UDP-glucuronyl-transferases	microsomal
–Sulfotransferases	cytosolic
–*N*-acetyltransferases	cytosolic
–Glutathione *S*-transferase	cytosolic/microsomal

2.5.3. *Role of Biotransformation in Detoxication and Bioactivation*

The general purpose of biotransformation reactions is detoxication, since xenobiotics should be transformed to metabolites which are more readily excreted. However, depending on the structure of the chemical and the enzyme catalyzing the biotransformation reaction, metabolites with a higher potential for toxicity than the parent compound are often formed. This process is termed bioactivation and is the basis for the toxicity and carcinogenicity of many xenobiotics with a low chemical reactivity (see Section Bioactivation of Xenobiotics). The interaction of the toxic metabolite initiates events that ultimately may result in cell death, cancer, teratogenicity, organ failure, and other manifestations of toxicity. Formation of reactive and more toxic metabolites is more frequently associated with phase-I reactions; however, phase-II reactions and combinations of phase-I and phase-II reactions may also be involved in toxication.

2.5.4. *Phase-I Enzymes and their Reactions*

Phase-I reactions are catalyzed by microsomal monooxygenases and peroxidases, cytosolic and mitochondrial oxidases, reductases, and hydrolytic enzymes. All these reactions add or expose functional groups which can be conjugated later.

2.5.4.1. *Microsomal Monooxygenases: Cytochrome P450*

Microsomal monooxygenases are the cytochrome P450 enzymes and the mixed-function amine oxidase or flavin-dependent monooxygenase. Both enzyme systems add a hydroxyl moiety to the xenobiotic. Cytochrome P450, a carbon monoxide binding hemoprotein in microsomes, is the most important enzyme system involved in phase-I reactions. The name cytochrome P450 is a generic term applied to a group of hemoproteins defined by the unique spectral property observed when reduced cytochrome P450 (Fe^{2+}) is treated with carbon monoxide. The complex formed has a maximum absorption at 450 nm imparted by the presence of an axial thiolate ligand on the heme iron atom. This spectral characteristic is only present when the protein is intact and catalytically functional. Denatured cytochrome P450 shows, like other heme proteins, an absorbance maximum at 420 nm.

Cytochrome P450 enzymes are a coupled enzyme system composed of the heme-containing cytochrome P450 and the NADPH-containing cytochrome P450 reductase [30]. This flavoprotein has a preference for NADPH as its cofactor and transfers one or two electrons from NADPH to cytochrome P450. Cytochrome P450 and the reductase are embedded into the phospholipid matrix of the endoplasmatic reticulum. The phospholipid matrix is crucial for enzymatic activity since it facilitates the interaction between the two enzymes. The importance of the phospholipid matrix is indicated by the following: Both cytochrome P450 and cytochrome P450 reductase can be purified to apparent homogeneity; the enzymatic activity of the purified and recombined enzymes is dependent on the addition of phospholipids.

In vertebrates, the highest concentrations of cytochrome P450 are found in the liver, but cytochrome P450 enzymes are also present in lung [31-35], kidney, testes, skin, and gastrointestinal tract [36]. The presence of several forms of cytochrome P450 with different substrate specificity and different rates of biotransformation for certain xenobiotics was indicated by studies in the 1970s. In the early 1980s, several different cytochrome P450 enzymes from rodents were purified to apparent homogenicity. Moreover, a large number of cytochrome P450 enzymes have been purified from human organs. All these cytochrome P450 enzymes share the heme, but they differ in both the composition and thus the structure of the polypeptide chain and in the reactions they catalyze [37-40].

The individual enzymes are regulated in their expression by a variety of factors such as treatment with xenobiotics, species, organ, sex, and diet. Because of the multitude of enzymes present, the term “superfamily” of cytochromes P450 is frequently used. In mammals, two general classes of cytochrome P450 exist: six families involved in steroid metabolism and bile acid biosynthesis, and four families containing numerous individual cytochromes P450, mainly responsible for xenobiotic biotransformation. A complex nomenclature, based on amino acid sequence similarity, has been developed to designate individual cytochromes P450. The

genes for the individual enzymes are named by the root CYP followed by a number designating the family, a letter for the subfamily, and another number denoting the individual enzyme (see Table 9).

Table 9. Mammalian cytochromes P450 involved in xenobiotic biotransformation

Family	Number of subfamilies	Number of forms
CYP1	1	2
CYP2	8	59
CYP3	2	11
CYP4	2	10

Reactions catalyzed by cytochrome P450. Cytochromes P450 are monooxygenases. They utilize one of the oxygen atoms of molecular oxygen and incorporate it into the xenobiotic RH:

$$RH + O_2 + NADPH + H^+ \rightarrow ROH + H_2O + NADP^+$$

The other oxygen atom is reduced to water with consumption of NADPH as reducing cofactor. The likely mechanisms of electron transfer and xenobiotic oxidation is shown in Figure 18.

Figure 18. Mechanisms of electron transfer and xenobiotic oxidation by cytochrome P450

In the first step of the catalytic cycle, the xenobiotic combines with the oxidized form of cytochrome P450 (Fe^{3+}) followed by a one-electron reduction by NADPH-cytochrome P450 reductase to form a reduced (Fe^{2+}) cytochrome P450-substrate complex. This complex then combines with molecular oxygen, and another electron from NADPH is accepted. In a series of further steps, which are not completely understood, an oxygen atom from the intermediate is transferred to the substrate, while the other oxygen atom is reduced to water. In the last step of the catalytic cycle, the oxidized substrate dissociates and regenerates the oxidized form of cytochrome P450. Examples for oxidation reactions catalyzed by cytochromes P450 are shown in Table 10.

Table 10. Oxidations catalyzed by cytochrome P450

Type of reaction	Examples
Aliphatic hydroxylation	$R-CH_2-CH_2-CH_3 \xrightarrow[P450]{O_2} R-CH_2-CHOH-CH_3$
N-Dealkylation	O-Dealkylation	Epoxidation	
Cytochromes P450 may catalyze the hydroxylation of carbon–hydrogen bonds to transform hydrocarbons to the corresponding alcohols. In larger aliphatic chains, the (ω – 1) position is often a favored point of attack. Oxidative *N*-, *O*-, or *S*-dealkylation and oxidative dehalogenation are similar in mechanism to aliphatic hydroxylation, but, due to further reactions of the intermediate products, give different end products. Olefins are also oxidized by cytochrome P450, and with some substrates, epoxides are formed as products. The reaction, however, does not proceed in a concerted manner, but involves discrete ionic intermediates, which may also rearrange to products other than epoxides, as shown for chloroolefins in Figure 19.

Figure 19. Mechanism of oxidation and rearrangement of trichloroethylene to chloral and trichlorooxirane, respectively

Oxidation at sulfur or nitrogen occurs by the addition of oxygen at the unshared electron pair on the sulfur or nitrogen atom. The products formed (sulfoxides or hydroxylamines) may be stable (many sulfoxides), may be further oxidized by other enzymes in the organism (e.g., hydroxylamines), or may decompose to sulfur and the corresponding oxo compound.

The above-mentioned reactions may be catalyzed by most cytochromes P450 involved in xenobiotic biotransformation; the type of reaction catalyzed seems to be more influenced by steric factors regarding the substrate-binding site of individual cytochromes P450 than by electronic factors. As shown in Table 11, which gives an overview of human cytochrome P450s involved in the biotransformation of xenobiotics and drugs, steric factors are likely major determinants of the substrate specificity of cytochrome P450 enzymes.

Table 11. Human cytochromes P450 identified as major catalysts in the biotransformation of specific xenobiotics that seem to play major roles in the oxidation of substrates listed

Cytochrome P450			
1A1	**1A2**	**2E1**	**3A4**
Benzo[*a*]pyrene	phenacetin	vinyl chloride	aflatoxin B_1
Other polycyclic hydrocarbons	1-aminofluorene	trichloroethylene	17- β-estradiol
	2-amino-3-methylimidazo-[4,5-*f*]quinoline	halothane benzene	6-aminochrysene sterigmatocystine
	2-naphthylamine	dimethylnitrosamine	nifedipine
		acetaminophen	ethinylestradiol

In addition to promoting oxidative metabolism, cytochrome P450 may also catalyze reductive biotransformation reactions [41, 42]. These reaction are favored under reduced oxygen pressure or occur with xenobiotics lacking oxidizable C—H bonds or olefinic moieties. In these cases,instead of oxygen, the xenobiotic accepts one or two electrons from NADPH-cytochrome P450 reductase or from cytochrome P450. Reductive biotransformation catalyzed by cytochrome P450 has been demonstrated with some azo dyes and several aromatic nitro compounds. The double bond in azo compounds may be progressively reduced to give amine metabolites; aromatic nitro groups may also be reduced via the nitrone and the hydroxylamine to the corresponding amine.

The reductive biotransformation of polyhalogenated alkanes is exemplified by the one-electron reduction of carbon tetrachloride to the trichloromethyl radical and chloride; reductive biotransformation of carbon tetrachloride by a two-electron reduction results in formation of chloroform:

2.5.4.2. *Microsomal Monooxygenases: Flavin-Dependent Monooxygenases*

Tertiary amines and sulfur-containing drugs have been known to be metabolized to *N*-oxides or sulfoxides by a microsomal monooxygenase which is not dependent on cytochrome P450 [43, 44]. This enzyme, which is historically referred to as mixed-function amine oxidase, is a flavoprotein that is present in the endoplasmatic reticulum. It is capable of oxidizing nucleophilic nitrogen and sulfur atoms in xenobiotics. However, this enzyme shows a catalytic mechanism different from those of other heme- or flavin-containing enzymes. Like other monooxygenases, flavin-containing monooxygenases require molecular oxygen and NADPH as cofactors for oxygenation. In contrast to the other monooxygenases, flavin-dependent monooxygenases do not contain heme or iron, and the binding of the substrate is not required for the generation of the enzyme bound oxygenating intermediate (Fig. 20).

Figure 20. Mechanism of xenobiotic oxidation by the flavin-dependent monooxygenase

FAD = flavineadenine dinucleotide

The active, oxygenating form of the enzyme is present in the cell, and any soft, oxidizable nucleophile that can gain access to the enzyme-bound oxygenating intermediate will be oxidized. Precise fit of substrate to the enzyme is not necessary. This property seems to be largely responsible for the broad substrate specificity of flavin-dependent monooxygenases. Flavin-dependent monooxygenase catalyzes the oxidation of a wide variety of xenobiotics with few, if any, common structural features at maximum rate (Table 12).

Table 12. Oxidations catalyzed by flavin-dependent monooxygenases

Type	Examples
Amine oxidation	Hydroxylamine oxidation	Thioamide oxidation	Thiol oxidation	$2R-SH \longrightarrow R-S-S-R$
Disulfide oxidation	$R-S-S-R \longrightarrow 2R-SO_2$

Many essential xenobiotics also bear functionalities that are oxidized by flavin-dependent monooxygenases. However, these enzymes apparently discriminate between physiologically essential and xenobiotic soft nucleophiles and seem to exclude the former.

As with cytochrome P450, species- and tissue-specific forms of flavin-dependent monooxygenase have been described. Species differences in hepatic flavin-dependent monooxygenase seem to be quantitative rather than qualitative, whereas tissue specific forms in the same species are clearly distinct enzymes. For example, hepatic and pulmonary flavin-dependent monooxygenases in rabbits exhibit distinct, but overlapping substrate specificities and are different gene products. Recent studies have shown that several isoforms of flavin-dependent monooxygenase exist; all isoforms show differences in their distribution in species and in organs within species [45].

The regulation of expression of flavin-dependent monooxygenase seems to be complex. Xenobiotics which were shown to increase the concentration of cytochrome P450 in mammals did not influence flavin-dependent monooxygenase concentrations. Recent evidence suggest that soft nitrogen and sulfur nucleophiles in the diet may act as inducers of flavin-dependent monooxygenases. Since the dietary inducers are continously taken up, flavin-dependent monooxygenases are present in maximal concentrations in rats on commercial rat chow.

2.5.4.3. *Peroxidative Biotransformation: Prostaglandin-synthase*

During the biosynthesis of prostaglandins, a polyunsaturated fatty acid, arachidonic acid, is oxidized to yield prostaglandin G_2, a hydroperoxy endoperoxide. This is further transformed to prostaglandin H_2. Both the formation of prostaglandin G_2 and its further transformation into prostaglandin H_2 are catalyzed by the same enzyme, prostaglandin synthase [46-48]. This enzyme is a glycoprotein with a molecular mass of approximately 70 000 Dalton and contains one heme per subunit. The enzyme is found in high concentrations in germinal vesicles and renal medulla, but also in several other tissues such as skin and adrenals [49]. The cyclooxygenase and peroxidase activity of prostaglandin synthase generate enzyme- and substrate-derived free-radical intermediates (Fig. 21).

Figure 21. Cooxidation of xenobiotics during the biosynthesis of prostaglandins

Biotransformation of xenobiotics may be associated both with the cyclooxygenase and the peroxidase activity of prostaglandin synthase (Fig. 21). During the cyclooxygenase-catalyzed conversion of arachidonic acid to prostaglandin G_2 peroxy radicals are formed as intermediates. These lipid peroxy radicals represent a source of reactive oxygen metabolites (see below) and can in turn biotransform xenobiotics. Oxidation by the cyclooxygenase activity of prostaglandin synthase is important in the oxidation of diols derived from carcinogenic polycyclic aromatic hydrocarbons and transforms these diols to diol epoxides (Fig. 21, top).

During the reduction of the peroxide prostaglandin G_2 to prostaglandin H_2, the peroxidase undergoes a two-electron oxidation. To return to the ground state the enzyme requires two consecutive one-electron reductions, which are achieved by abstracting electrons from available donors. In addition to endogenous substrates, xenobiotics may act as electron donors and may thus be oxidized to radicals (Fig. 21, bottom). This process is termed cooxidation of xenobiotics. Classes of xenobiotics that undergo cooxidation during prostaglandin syntheses are aromatic amines, phenols, hydroquinones, and aminophenols. The role of prostaglandin synthase in the biotransformation of xenobiotics is somewhat unclear, since many of the end products of prostaglandin-synthase-mediated cooxidation of xenobiotic are identical to those formed by cytochrome P450. Therefore, it is assumed that prostaglandin synthase may contribute to the oxidative biotransformation of xenobiotics in tissues low in monooxygenase activity [50].

In addition to prostaglandin synthase, other peroxidases may also participate in the oxidation of xenobiotics [51-53]. For example, mammary gland epithelium contains lactoperoxidase and leucocytes contains myeloperoxidase. The general reaction catalyzed by this enzymes involves the reduction of hydroperoxide coupled to the oxidation of the substrate:

$$\mathrm{ROOH + XH \rightarrow ROH + XOH}$$

The availability of peroxides in tissues likely controls the extent of peroxidative biotransformation; however, the availability of hydrogen peroxide is usually low due to efficient scavenging by catalase and glutathione peroxidase. Therefore, peroxidative metabolism occurs mainly in tissues which can maintain an oxidizing environment.

2.5.4.4. *Nonmicrosomal Oxidations*

Several enzymes located in mitochondria or the cytoplasm of the cell may also catalyze the oxidation of xenobiotics. In contrast to cytochromes P450 with their broad substrate specificity, most of the nonmicrosomal oxidases have a more narrow substrate specificity and accept only xenobiotics bearing specific functional groups as substrates. Alcohol dehydrogenases catalyze the oxidation of alcohols to aldehydes or ketones:

$$\mathrm{RCH_2OH + NAD^+ \rightarrow RCHO + NADH + H^+}$$

The enzyme is mainly found in the soluble fraction of liver, but also in other organs such as the kidney and lung and is responsible for the oxidation of ethanol. The expression of alcohol dehydrogenase is under genetic control, which gives rise to a number of variants with differing activities. Usually, the oxidation of alcohols to aldehydes is reversible, since the reduction of aldehydes is also efficiently catalyzed by aldehyde reductases. However, in vivo, the reaction proceeds in the direction of alcohol consumption since aldehydes are further oxidized by aldehyde dehydrogenases. These enzymes catalyze the formation of acids from aliphatic and aromatic aldehydes:

$$\mathrm{RCHO + NAD^+ \rightarrow RCOOH + NADH + H^+}$$

The reaction may be catalyzed by aldehyde dehydrogenase, which has broad substrate specificity, and several isozymes of aldehyde dehydrogenase are found in liver cytosol, mitochondria, and microsomes with characteristic substrate specificities. Other enzymes in the soluble fraction of liver that can oxidize aldehydes are the flavoproteins aldehyde oxidase and xanthine oxidase.

Monoamine oxidases are a family of flavoproteins present in many tissues including liver, kidney, brain, and intestine. These mitochondrial enzymes have a broad and overlapping substrate specificity and oxidize a variety of amines:

$$\mathrm{RCH_2NH_2 + O_2 + H_2O \rightarrow RCHO + NH_3 + H_2O}$$

The monoamine oxidase found in the central nervous system is concerned primarily with neurotransmitter turnover.

2.5.4.5. *Hydrolytic Enzymes in Phase-I Biotransformation Reactions*

Many tissues contain enzymes with carboxylesterase and amidase activity. These enzymes are located both in microsomal and soluble fraction and hydrolyse ester and amide linkages in xenobiotics.

Although esterases and amidases were thought to be different enzymes, all purified esterases have been demonstrated to have amidase activity; similarly, all amidases have esterase activity. In general, esters are cleaved more rapidly than amides. The expression of many esterases is under genetic control; thus, extremes of high/low esterase activity and resistance/sensitivity to toxic effects mediated by esterases are known.

Epoxide hydrolase is an important enzyme cleaving aliphatic and aromatic epoxides. The enzyme hydrates arene oxides and aliphatic epoxides to the corresponding *trans*-1,2-diols [54]. Water is required as cofactor, and the catalytic mechanism of epoxide hydrolases involves ester formation of the oxirane with a carboxylic acid function at the active site of the enzyme and hydrolysis of this ester by water; no metals or other cofactors are required.

Microsomal epoxide hydrolases are thought to be present in close proximity to the microsomal cytochromes P450; in most cases, the conversion of the epoxide to the less reactive diol is considered to represent an important detoxication reaction for metabolically formed oxiranes. Epoxide hydrolases are found in many tissues such as liver, kidney, testes, and intestine. Their distribution is heterogenous between different cell types in a specific organ; in addition, several forms of microsomal epoxide hydrolases with broad substrate specificity have been found in different animal species. Moreover, in animals, in addition to membrane-bound epoxide hydrolase, a soluble epoxide hydrolase is present in cytoplasm of several tissues [55].

2.5.5. ***Phase-II Biotransformation Enzymes and their Reactions***

Products of the phase-I biotransformation reactions carrying functional groups such as hydroxyl, amino, or carboxyl often undergo a conjugation reaction with an endogenous substrate. The endogenous substrates may include sugar derivatives, sulfate, amino acids, and small peptides (glutathione). The conjugation products are usually more polar and thus more readily excreted than their parent compounds.

In contrast to phase-I biotransformation reactions, phase-II reactions are biosynthetic and require energy to drive the reaction. Energy is usually consumed to generate a high-energy cofactor or an activated intermediate and then utilized as cosubstrate. Thus, depletion of the cofactor or general interference with cellular energy status may interfere with the ability of cells to conduct phase-II biotransformation reactions.

2.5.5.1. *UDP-Glucuronyl Transferases*

Glucuronidation represents one or the main phase-II biotransformation reactions in the conversion of both endogenous and exogenous compounds to water soluble products [56-59]. The formed glucuronides are excreted with bile or urine. The formation of an activated glucuronide (uridine diphosphate glucuronic acid, UDPGA), is required for glucuronide formation. UDPGA is formed in a sequential reaction from uridine and glucose-1-phosphate.

$$\text{Uridine triphosphate} + \text{Glucose 1-phosphate} \xrightarrow[\text{Pyrophosphorylase}]{\text{UDPG}} \text{Uridine diphosphate glucose} + \text{Pyrophosphate}$$

$$\text{Uridine diphosphate glucose} + 2\,NAD^+ + H_2O \xrightarrow{\text{Dehydrogenase}} UDPGA + 2\,NADH_2$$

The enzymes that carry out the coupling of the xenobiotic with UDPGA are termed UDP-glucuronyl transferases. They couple D-glucuronic acid with a wide variety of xenobiotics carrying functional groups to give β-D-glucuronides [57]. These glucuronides are highly polar and ionized at physiological pH, and hence are rapidly excreted. The membrane-bound UDP-glucuronyl transferases are found in highest concentration in the liver, but also in most other tissues studied. The reaction catalyzed involves a nucleophilic displacement (S_N2) of the functional group of the substrate with Walden inversion (Fig. 22).

Figure 22. Conjugation of phenol to phenyl glucuronide catalyzed by UDP-glucuronyltransferase (UDP = uridine diphosphate)

UDP-glucuronyl transferases, like cytochrome P450, represent a family of enzymes, and at least ten individual forms are known. The various forms respond differently to inducers and have preferences for certain classes of chemicals. UDP-glucuronyl transferases catalyze the conjugation of numerous functional groups of xenobiotics with glucuronic acids. Some typical examples are shown in Table 13.

Table 13. Typical conjugation reactions catalyzed by UDP-glucuronyltransferases

Type of reaction	Examples
O-Glucuronide formation	N-Glucuronide formation	S-Glucuronide formation	
Glucuronides formed in the liver are excreted with urine or bile. Aglycones with molecular masses higher than 300 are transformed to glucuronides that surpass the molecular mass threshold for biliary excretion (see Section Hepatic Excretion) and will thus be excreted with bile into the intestine. Glucuronides may by cleaved there by β-glucuronidase present in intestinal microflora to the respective aglycone, which may be reabsorbed from the intestine and translocated back to the liver with the blood. The resulting cycle is called enterohepatic circulation; compounds that undergo enterohepatic circulation are only slowly excreted and usually have a longer half-life in the body.

2.5.5.2. *Sulfate Conjugation*

The formation of water-soluble sulfate esters is observed with many xenobiotics carrying functional groups such as alcohols, phenols, and arylamines. These reactions are catalyzed by sulfotransferases, a large group of soluble enzymes found in many tissues [60-62]. Sulfotransferases catalyze the transfer of a sulfate group from the “active sulfate” 3′-phosphoadenosine-5′-phosphosulfate to hydroxyl groups and amines. The resulting products are referred as sulfate esters of sulfamates.

The products of this reaction are ionized at physiological pH and may therefore be rapidly excreted in urine; thus, sulfate conjugation is an effective mechanism to enhance the rate of excretion of many xenobiotics. Sulfotransferases are also a family of enzymes, and at least four different classes of sulfotransferases are involved in biotransformation reactions: sulfotransferases, hydroxysteroid sulfotransferases, estrone sulfotransferases, and bile salt sulfotransferases; each class again has been divided into several distinct forms differing in substrate specificity, optimum pH and immunological properties.

Sulfate conjugation also requires a sulfate donor, 3′-phospho-adenosine-5′-phosphosulfate. 3′-Phospho-adenosine-5′-phosphosulfate is likely synthesized in the cytosol of most mammalian cells by a two-step reaction consuming ATP and utilizing inorganic sulfate originating from the catabolism of cysteine or from diet. In the first step of this sequence the sulfation of ATP to adenosine 5′-phosphosulfate is catalyzed by an ATP sulfurylase. Adenosine 5′-phosphosulfate is further transformed to 3′-phospho-adenosine 5′-phosphosulfate by an adenosine 5′-phosphosulfate kinase. However, the equilibrium concentration of 3′-phosphoadenosine 5′-phosphosulfate in mammalian cells may be low, and due to the tight coupling of two enzymes in 3′-phosphoadenosine 5′-phosphosulfate, biosynthesis may proceed rapidly.

$$SO_4^{2-} + ATP \xrightarrow{\text{Sulfurylase}} APS + \text{Pyrophosphate}$$

$$APS + ATP \xrightarrow[\text{phosphokinase}]{\text{APS-}} PAPS + ADP$$

Despite the rapid synthesis, the sulfation of xenobiotics may by limited by reduced availability of 3′-phosphoadenosine 5′-phosphosulfate. The availability of the cofactor of the synthesis reaction, sulfate, may be limited by consumption due to sulfation or the limited availability of free cysteine for transformation to sulfate. Therefore, the sulfation capacity for certain xenobiotics is dependent on dose. Following administration of low doses the compound may be excreted as sulfate; after high doses, the capacity of sulfate conjugation may be saturated, and other biotransformation reactions such as glucuronide formation may become more important for biotransformation.

2.5.5.3. *Methyl Transferases*

A large number of alcohols, phenols, amines, and thiols present both as endogenous and exogenous compounds may be methylated by several *N*-, *O*- and *S*-methyl transferases. The most common donor for the methyl group is *S*-adenosyl methionine, which is formed from methionine and ATP. Often, these reactions do not increase the water solubility of a xenobiotic, but they are regarded as phase-II reactions since they mask potentially toxic functional groups and thus may serve as detoxication reactions.

A large variety of enzymes catalyze methylations of xenobiotics. The more important enzymes involved in methylation reactions are usually found in many tissues and are present in the soluble fraction of tissues. Some of the enzymes have a high specificity for certain endogenous compounds such as histamine or noradrenaline; others, such as catechol *O*-methyl transferase, metabolize both endogenous catechols and certain xenobiotics carrying aromatic rings with catechol functionalities [63].

2.5.5.4. *N-Acetyl Transferases*

Aromatic amines, hydrazines, sulfonamides, and certain aliphatic amines are biotransformed into amides in a reaction catalyzed by *N*-acetyl transferases. Enzymes that catalyze the acetylation of amines are designated as acetyl CoA: amine *N*-acetyl transferases. These enzymes utilize acetyl coenzyme A as cofactor [64]. The acetylation reaction of arylamines occurs in discrete steps. In the first step, the acetyl group from acetyl coenzyme A is transferred to the *N*-acetyl transferase, which then acetylates the arylamine, thus regenerating the enzyme and forming the amide (Fig. 23).

Figure 23. Mechanism of the *N*-acetylation of amines by *N*-acetyl transferase

N-Acetyl transferases are found in a number of different forms in cytosol of many tissues. In many species, the expression of *N*-acetyl transferases is under genetic control, and polymorphism for the expression of *N*-acetyl transferase has been found in several animal species and in humans. The transfer of an acetyl group to amines is reversible, and deacetylation of amides occurs in many species; as noted above, there are large differences between strains, species, and individuals in the extent of expression of amidases [65].

2.5.5.5. *Amino Acid Conjugation*

Exogenous carboxylic acids are conjugated with a variety of amino acids to form amides. Substrates for conjugation are mainly carboxylic acids containing aromatic rings. Glutamate and glycine appear to be the most common amino acids involved in these conjugation reactions in mammals; in other species such as reptiles and birds, ornithine is involved. The reaction proceeds in two steps and is catalyzed to two different enzymes. In the first step, the carboxylic acid is activated to form a coenzyme A derivative in a reaction involving coenzyme A and ATP. The enzymes that catalyze this reaction are called ATP-dependent acid coenzyme A ligases and are present in mitochondria. They appear to be identical to the intermediate-chain-length fatty acid:coenzyme A synthetase. The thus-formed coenzyme A thioester then transfers its acyl group to the amino group of the acceptor amino acid. This reaction is catalyzed by an *N*-acetyl transferase (Fig. 24). The enzymes catalyzing both steps in amino acid conjugation exist in several forms with different substrate specifities.

Figure 24. Amino acid conjugation of a xenobiotic carboxylic acid by ATP-dependent acid- coenzyme A ligases followed by *N*-acetyltransferase

2.5.5.6. *Glutathione Conjugation of Xenobiotics and Mercapturic Acid Excretion*

The conjugation of xenobiotics or their metabolites with the tripeptide glutathione is an important conjugation reaction. Glutathione is composed of the amino acids cysteine, glutamic acid, and glycine (ϒ-glutamylcysteinylglycine) and is present in many cells in high concentrations (up to 10 mM in liver cells) [66]. Since glutathione conjugation captures reactive electrophiles and transforms them into stable, often nontoxic thioethers, the formation of glutathione conjugates protects cells from the harmful effects of these electrophiles and thus serves as a major detoxication reaction (Section Detoxication and Interactions of Reactive Metabolites with Cellular Macromolecules). Glutathione conjugation is catalyzed by a family of enzymes termed glutathione *S*-transferases, which are present in the highest concentration in the liver, but are also found in high activity in the kidney, testes, and lung [67]. Glutathione *S*-transferases exist in both membrane-bound and soluble forms; with most substrates, the activity of soluble glutathione *S*-transferase is higher than that of microsomal glutathione *S*-transferase [68].

Cytosolic glutathione *S*-transferases exist in numerous different isoforms, each species being a dimer differing in subunit composition [67, 69]. The glutathione *S*-transferase gene family exists of at least six different families. In contrast to the multiple forms of soluble glutathione *S*-transferases thus possible, only one form of the membrane-bound enzyme is known. The glutathione *S*-transferases catalyze the reaction of the sulfhydryl group of glutathione with chemicals containing electrophilic carbon atoms (Table 14).

Table 14. Substrates for mammalian glutathione S-transferases

GSH = Glutathione. ** GS = Glutathionyl residue.

Thioethers are formed by reaction of the thiolate anion of glutathione with the electrophile; a spontaneous reaction, albeit at low rates, of the electrophile with glutathione without assistance by glutathione *S*-transferases is required for enzymatic catalysis. Glutathione thioethers formed in the organism are not excreted, but further processed to excretable mercapturic acids. Mercapturic acids are thioethers derived from *N*-acetyl-L-cysteine. Mercapturic acid formation is initiated by conjugation of the xenobiotic or an electrophilic metabolite with glutathione (Fig. 25).

Figure 25. Formation of mercapturic acids by processing of glutathione *S*-conjugates as exemplified by the metabolism of methyl iodide

This is followed by transfer of the glutamate by ϒ-glutamyltranspeptidase, an enzyme specifically recognizing ϒ-glutamyl peptides and found in high concentrations in the kidney and other excretory organs. Dipeptidases catalyze the loss of glycine from the intermediary cysteinylglycine *S*-conjugate to give the cysteine *S*-conjugate which, in the final step of mercapturic acid formation, is *N*-acetylated by a cysteine-conjugate-specific *N*-acetyltransferase using acetyl coenzyme A as cofactor. The mercapturic acids formed are readily excreted into urine by active transport mechanisms in the kidney [70].

Glutathione conjugation is one of the most important detoxication reactions for reactive intermediates formed in organisms. Usually, metabolically formed intermediates are efficiently detoxified, but under specific circumstances, glutathione conjugation may be overwhelmed by high concentrations of electrophiles, which result in covalent binding of intermediates to cellular macromolecules, disruption of important cellular functions, and cell death and necrosis (see Section Hydrolytic Enzymes in Phase-I Biotransformation Reactions).

2.5.6. *Bioactivation of Xenobiotics*

Many xenobiotics with low chemical reactivity (e.g., the solvent carbon tetrachloride, the environmental contaminant hexachlorobutadiene, and the heat-exchanger fluid tri-*o*-cresyl phosphate) cause toxic effects. These toxic effects are initiated by covalent binding to macromolecules of metabolites formed in the organism by biotransformation enzymes. This process is termed bioactivation. With many chemicals, reactive metabolites formed during bioactivation may be efficiently detoxified; thus, toxic effects only occur when the balance between the production of reactive metabolites and their detoxication is disrupted. For example, toxic effects may be observed with a certain chemical only when the formation of reactive intermediates is enhanced or when the capacity for detoxication is diminished.

The mechanisms of bioactivation of xenobiotics may be classified into four categories describing the basic types of reactive intermediates formed and their potential reactivity (Table 15) [71-73].

Table 15. Basic mechanisms involved in the bioactivation of xenobiotics based on chemical reactivity of intermediates formed

Mechanism	Structure and reactivity of the intermediate	Examples
Biotransformation to stable but toxic metabolites	different structures, selective interaction of formed metabolite with specific acceptors, or disruption of specific biochemical pathways	dichloromethane, acetonitrile, parathion
Biotransformation to electrophiles	reactive electrophiles	dimethylnitrosamine, acetaminophen, bromobenzene
Biotransformation to free radicals	radicals	carbon tetrachloride
Formation of reactive oxygen metabolites	radicals	paraquat, aromatic nitro compounds

2.5.6.1. *Formation of Stable but Toxic Metabolites*

This mechanisms is limited to a few selected chemicals because few xenobiotic metabolites are both stable and toxic. The bioactivation of the solvents *n*-hexane and dichloromethane are examples of this mechanism. *n*-Hexane produces a characteristic neuropathy and peripheral nerve injury after chronic exposure. The same typical manifestations of toxicity are also observed when the *n*-hexane metabolites 2-hexanone and 2,5-hexanedione are administered to animals. The mechanism of *n*-hexane neuropathy thus involves oxidation of *n*-hexane by cytochromes P450 at both ends of the carbon chain (ω–1 hydroxylation) and further oxidation of the thus-introduced alcoholic function. The 2,5-hexanedione formed reacts with critical lysine residues in axonal proteins by Schiff base formation followed by cyclization to give pyrroles [74]. Oxidation of the pyrrole residues then causes crosslinking between two *n*-hexane-modified proteins; the resulting changes in the three-dimensional structures of proteins perturb axonal transport and function and cause damage to nerve cells (Fig. 26).

Figure 26. Bioactivation of hexane by cytochrome P450 to 2,5-hexanedione

Hexanedione reacts with lysine groups in proteins to form pyrroles; oxidation of two neighboring pyrrole residues causes the cross-linking of proteins.

Carboxyhemoglobin formation is observed after human exposure to dichloromethane. Dihalomethanes are oxidized by cytochrome P450, likely by P450 2E1, to carbon monoxide, which, due to its high affinity for iron(II)-containing porphyrins, binds to hemoglobin and interferes with oxygen transport in the blood. Other examples for the formation of stable, but toxic metabolites include the oxidation of acetonitrile to cyanide

and the oxidative desulfuration of parathion.

Parathion is a potent insecticide acting as an inhibitor of cholinesterase, but itself is only a weak cholinesterase inhibitor. Biotransformation of parathion by oxidative desulfuration to give the potent cholinesterase inhibitor paraoxone is responsible for the high insecticidal potency.

2.5.6.2. *Biotransformation to Reactive Electrophiles*

Biotransformation to reactive electrophiles is the most common pathway of bioactivation. The cytotoxicity and carcinogenicity of many chemicals is associated with the formation of electrophiles and the ensuing alkylation or acylation of tissue constituents such as protein, lipid, or DNA. Reactive intermediates include such chemically diverse functionalities as epoxides, quinones, acyl halides, carbocations, and nitrenium ions. The metabolic formation of electrophiles may be catalyzed by many different enzymes, although the majority of cases elucidated to date involve cytochrome P450-mediated oxidations.

Cytochrome P450 catalyzes the transformation of olefins to reactive and electrophilic oxiranes. For example, the carcinogenicity of the industrial intermediate vinyl chloride (Fig. 27) and the fungal toxin vaflatoxin B1 (Fig. 28) are dependent on their transformation to electrophilic oxiranes [75, 76].

Figure 27. Bioactivation of vinyl chloride to chlorooxirane and reaction of the epoxide with critical macromolecules in the cell

dR = Deoxyribose

Figure 28. Bioactivation of aflatoxin B_1 to an electrophilic oxirane which results in the formation of DNA adducts and is believed to initiate tumor induction by aflatoxin B_1 in the liver

Carbocations are formed during the cytochrome P450-mediated oxidation of dialkyl nitrosamines. For example, the mutagen and potent carcinogen dimethylnitrosamine is hydroxylated by cytochrome P450 followed by loss of formaldehyde. Monomethylnitrosamine thus formed is unstable and rearranges to release an electrophilic carbocation (Fig. 29).

Figure 29. Bioactivation of dimethylnitrosamine to a methylating agent by cytochrome P450

Acyl halides are formed by the oxidation of carbon atoms bearing at least two halogen atoms. The initially formed products are unstable α-halohydrins, which lose hydrogen chloride and thus give reactive acyl halides. An example for the formation of acyl halides as reactive intermediates is the cytochrome P450-mediated oxidation of chloroform to phosgene [77] (Fig. 30).

Figure 30. Bioactivation of chloroform by cytochrome P 450 mediated hydroxylation of a C — H bond

However, besides cytochromes P450, other monooxygenases such as flavin-dependent monooxygenase and of phase-II biotransformation enzymes such as UDP-glucuronyl transferases, sulfotransferases, or even the glutathione *S*-transferases may catalyze the bioactivation of xenobiotics [78]. For example, *N*-acetylamidofluorene is oxidized to *N*-hydroxyacetylamidofluorene by cytochrome P450. However, this metabolite is not electrophilic and requires further biotransformation via sulfate conjugation to the highly reactive *O*-sulfate ester. This sulfate ester fragments to a reactive intermediate (a nitrenium ion) which covalently binds to tissue constituents such as DNA (Fig. 31).

Figure 31. Bioactivation of acetylamidofluorene by cytochrome P450 and by UDP glucuronyl transferases. The glucuronide formed is acid-labile and decomposes to a nitrenium ion.

Some glutathione *S*-conjugates which are biosynthesized to detoxify electrophiles are toxic and mutagenic [79, 80]. 1,2-Dibromoethane is metabolized by glutathione conjugation to *S*-(2-bromoethyl)glutathione. Intramolecular displacement of the bromine on the adjacent carbon atom gives a highly strained, electrophilic episulfonium ion (Fig. 32).

Figure 32. Bioactivation of 1,2-dibromoethane by glutathione conjugation to a reactive and electrophilic episulfonium ion

Other toxic glutathione *S*-conjugates require processing by the enzymes of mercapturic acid formation to give electrophiles. A minor pathway in perchloroethene biotransformation results in *S*-(1,2,2-trichlorovinyl)glutathione [81]. This glutathione *S*-conjugate is cleaved by γ-glutamyl transpeptidase and dipeptidases to *S*-(1,2,2-trichlorovinyl)-L-cysteine, which is a substrate for renal cysteine conjugate β-lyase and transformed to pyruvate, ammonia, and a reactive thioketene, binding of which to cellular macromolecules is likely responsible for the renal toxicity of perchloroethene (Fig. 33).

Figure 33. Bioactivation of perchloroethene by glutathione conjugation. The conjugate *S*-(1,2,2-trichlorovinyl)glutathione is biosynthesized in the liver, translocated to the kidney to be processed by γ-glutamyl transpeptidases and dipeptidases, and finally cleaved by cysteine-conjugate β-lyase to give dichlorothioketene.

Due to high concentrations of *S*-(1,2,2-trichlorovinyl)-L-cysteine obtained by active transport to the kidney, covalent binding of the dichlorothioketene formed via this pathway occurs only in the kidney; despite the presence of cysteine conjugate β-lyase in many other organs.

2.5.6.3. *Biotransformation of Xenobiotics to Radicals*

Free radicals are chemical species that may be formed by a one-electron oxidation to give a radical cation, by a one-electron reduction to give a radical anion, or by homolytic fission of a σ-bond to give a neutral radical.

Free radicals are highly reactive and, when formed in biological systems, are expected to react with a variety of tissue molecules. Radicals may abstract hydrogen atoms, undergo oxidation-reduction reactions, dimerizations and disproportionation reactions. Radicals may also participate in a chain mechanism, which is initiated by a reaction causing a free radical and propagated by a subsequence of reactions causing further radicals as products.

The toxic and tumorigenic solvent carbon tetrachloride is the outstanding example of a bioactivation reaction to a free radical. Carbon tetrachloride is biotransformed by a one-electron reduction to yield the trichloromethyl radical and chloride:

$$Cl_4C + e^- \rightarrow Cl_3C^\bullet + Cl^-$$

The trichloromethyl radical may abstract hydrogen atoms from tissue macromolecules to give chloroform, a proven metabolite of carbon tetrachloride, or may dimerize to give hexachloroethane, which is also a metabolite of carbon tetrachloride. Toxic effects of radicals formed during biotransformation reactions are lipid peroxidation and oxidative modification of proteins (see Section Formation of Reactive Oxygen Metabolites by Xenobiotics). Formation of radicals has been implicated in the bioactivation of many xenobiotics. Radicals may be formed by NADPH-dependent cytochrome P450 reductase, nitroreductases, or one-electron oxidations catalyzed by peroxidases such as prostaglanding synthetases. Formation of free radicals from tissue constituents also plays an important role in the toxic effects of ionizing radiation [82-85].

2.5.6.4. *Formation of Reactive Oxygen Metabolites by Xenobiotics*

Xenobiotic-induced formation of reduced oxygen metabolites such as the superoxide radical anion, hydrogen peroxide, and the hydroxyl radical has been implicated as a mechanism of producing cell damage, so-called oxidative stress [86-89]. The biotransformation of certain xenobiotics that are involved in redox cycles or undergo enzyme-catalyzed oxidation/reduction reactions may be associated with the production of reduced oxygen metabolites. 2-Methylnaphthoquinone (Menadione) has been intensively used to study the formation and cellular reactions of reduced oxygen metabolites. Menadione and other quinones undergo enzymatic redox cycling; these one-electron oxidation reactions are associated with the formation of the superoxide radical anion ($O^{\cdot 2-}$) by one electron reduction of triplet oxygen. In aqueous solution, superoxide is not particularly reactive, but dismutation or further reduction of superoxide may give rise to hydrogen peroxide (Fig. 34).

Figure 34. Biotransformation of menadione and induction of oxidative stress by reduction of triplet oxygen to the superoxide radical anion

Hydrogen peroxide is also a poor oxidant in biological systems, but sufficiently stable to cross biological membranes. The toxicity of hydrogen peroxide is attributed to the formation of the hydroxyl radical by the Fenton reaction, catalyzed by metal ions such as Fe^{2+} (M = transition metal):

$$M^n + H_2O_2 \rightarrow M^{(n+1)} + HO^\bullet + HO^-$$

The highly reactive hydroxyl radical may then initiate cellular damage by radical-based mechanisms. Besides menadione, oxidative stress may also be initiated by other xenobiotics such as the bis-pyridinium herbicide paraquat and nitroheterocycles. Moreover, the formation of reduced oxygen metabolites plays an important role in host defense against infectious agents and in the initiation and propagation of certain diseases such as arteriosclerosis and polyarthritis.

Since oxygen radicals are also formed in low concentrations during cellular respiration, efficient mechanisms for their detoxication exist (see Section Detoxication and Interactions of Reactive Metabolites with Cellular Macromolecules). Oxidative stress is thus only observed when the eqilibrium between oxidants and reductants is disturbed and detoxication mechanisms are overwhelmed.

2.5.6.5. *Detoxication and Interactions of Reactive Metabolites with Cellular Macromolecules*

Reactive intermediates formed inside cells may react with low and high molecular mass cellular constituents. These interactions may result in formation of less reactive chemicals and thus in detoxication, or may perturb important cellular functions and thus result in acute and/or chronic toxic effects such as necrosis or cancer. Usually, the interaction with low molecular mass constituents in the cell results in detoxication, whereas the irreversible interaction with cellular macromolecules results in adverse effects [70, 90-92].

Detoxication of reactive intermediates may be due to hydrolysis, glutathione conjugation, or interactions with cellular antioxidants. The reaction of electrophilic xenobiotics with the nucleophile water, present in high concentrations in all cells, is the simplest form of detoxication. Many of the products thus formed are of low reactivity and may be rapidly excreted. For example, acyl halides formed by the oxidation of olefins such as perchloroethylene are hydrolyzed rapidly to halogenated carboxylic acids; only minor amounts of the intermediate acyl halide reacts with protein and lipids (Fig. 35).

Figure 35. Biotransformation of tetrachloroethylene to trichloroacetyl chloride followed by hydrolysis to trichloroacetic acid, the major urinary metabolite formed from tetrachloroethylene. Only a small amount of the acyl halide formed reacts with proteins.

Glutathione-dependent detoxication is an important mechanism for metabolically formed electrophiles, free radicals, and reduced oxygen metabolites [93-96]. Electrophiles react with the nucleophilic sulfur atom of glutathione in a spontaneous or enzyme-catalyzed reaction. Spontaneous reactions are only observed at appreciable rates with soft electrophiles (glutathione is a soft nucleophile); the conjugation of hard electrophiles with glutathione requires enzymatic catalysis; usually, the rates of conjugation catalyzed by glutathione *S*-transferase differ between hard and soft electrophiles; soft electrophiles are conjugated more efficiently. For example, the hard electrophile aflatoxin B_1 8,9-oxide does not spontaneously react with glutathione; only in the presence of a certain glutathione *S*-transferase

enzyme is a glutathione *S*-conjugate of aflatoxin B_1 8,9-oxide formed. Species differences in the tumorigenesis of aflatoxin B_1 may serve to illustrate the important role of glutathione *S*-transferases in the expression of toxicity and carcinogenicity. Aflatoxin B_1 is a potent liver carcinogen in rats; in mice, aflatoxin B_1 is only weakly carcinogenic. The liver of mice contains a glutathione *S*-transferase which efficiently detoxifies aflatoxin B_1 8,9-oxide. This glutathione *S*-transferase enzyme is not present in rat liver; thus, the binding of aflatoxin B_1 8,9-oxide to rat liver DNA and liver carcinogenicity of aflatoxin B_1 are much higher in rats than in mice.

Glutathione also plays a major role in the detoxication of reactive oxygen metabolites and radicals. Selenium-dependent glutathione peroxidases are important enzymes catalyzing the detoxication of hydrogen peroxide. In the glutathione peroxidase catalyzed reaction, two moles of glutathione are oxidized to glutathione disulfide:

$$H_2O_2 + 2\,GSH \underset{\text{Glutathione reductase}}{\overset{\text{Glutathione peroxidase}}{\rightleftharpoons}} GSSG + H_2O$$

Glutathione can be recycled by the reduction of glutathione disulfide by glutathione reductase.

The copper- and zinc-dependent cytosolic and - manganese-dependent mitochondrial superoxide dismutases detoxify superoxide radical anions. Hydrogen peroxide formed by dismutation of superoxide is converted to water and oxygen and thus detoxified by catalase:

$$2\,H_2O_2 \xrightarrow{\text{Catalase}} 2\,H_2O + \tfrac{1}{2}\,O_2$$

Several cellular antioxidants also play a role in the detoxication of radicals. α-Tocopherol is an important lipophilic antioxidant, whose presence in lipid membranes prevents damage to lipid constituents (e.g. unsaturated fatt acids) by radicals. The hydroxyl radical, the superoxide radical anion, and peroxy radicals react with α-tocopherol to yield water, hydrogen peroxide, and hydroperoxides, which may be detoxified further by catalase and glutathione peroxidase. α-Tocopherol is transformed during these reactions to give a stable radical of comparatively low reactivity. Ascorbic acid is an important antioxidant present in the cytoplasm of the cell and may also participate in the detoxication of radicals.

2.5.6.6. *Interaction of Reactive Intermediates with Cellular Macromolecules*

Although a substantial body of information is available on the biotransformation of xenobiotics to reactive metabolites and the chemical nature of those metabolites, considerably less is known about how reactive intermediates interact with cellular constituents and how those interactions cause cell injury and cell death. The reaction of toxic metabolites may result in the formation of covalent bonds between the molecule and a cellular target molecule, or they may alter the target molecule without formation of a covalent bond, usually by oxidation or reduction [97].

Electrophilic metabolites may react with different nucleophilic sites in cells. Nucleophilic sites in cellular macromolecules are thiol and amino groups in proteins, amino groups in lipids, and oxygen and nitrogen atoms in the purine and pyrimidine bases of DNA. The formation of a covalent bond may permanently alter the structure and/or activity of the modified macromolecule and thus result in a toxic response. The complexity of the reaction of electrophilic metabolites with the various nucleophilic sites in cells may be interpreted on the basis of the concept of hard and soft electrophiles and nucleophiles (hard and soft acids and bases). The donor atom of a soft nucleophile is of high polarizability and low electronegativity, and is easily oxidized; the donor atom of a hard nucleophile is of low polarizability and high electronegativity. Hard electrophiles carry a high positive charge and have a small size; soft electrophiles are of low positive charge and large size. Soft electrophiles react predominantly with soft nucleophiles, and hard electrophiles with hard nucleophiles [98]. Thus, hard electrophiles formed during a biotransformation reaction (e.g., carbocations formed from dialkylnitrosamines) predominantly react with hard nucleophiles such as the oyxgen and nitrogen atoms of DNA, In contrast, soft electrophiles such as α, β-unsaturated carbonyl compounds (e.g., acrolein, benzoquinone) react predominatly with soft tissue nucleophiles such as the sulfhydryl groups of cysteine in proteins (Table 16).

Table 16. Metabolically formed electrophiles and their prime targets for covalent binding in cells

Soft		→		**Hard**
		Nucleophile		
SH of cysteine or glutathione	sulfur of methionine	primary or secondary nitrogen atoms in peptides (lysine, arginine, or histidine)	amino groups of purines and pyrimidines in RNA and DNA	oxygen in purines and pyrimidines in DNA and RNA
		Electrophile		
α, β-Unsaturated carbonyls, quinones	epoxides, alkyl sulfates, alkyl halides	nitrenium ions	benzylic carbocations	aliphatic and aromatic carbocations

Covalent interactions of xenobiotics with proteins occur with several nucleophilic nitrogen atoms; both alkylation and acylation reactions of amino acids have been reported as consequences of formation of reactive intermediates in cells. Besides the sulfur atom of cysteine, nitrogen atoms in the amino acids lysine, histidine, and valine are frequent targets for electrophilic metabolites. Consequences of the modifications may be inactivation of enzymes important for cellular function, changes in the tertiary structure of proteins, or changes in gene expression. Alkylation of the sulfhydryl-dependent enzymes of mitochondrial respiration is thought to play an important role in the initiation of mitochondrial dysfunction and thus cell damage.

Some modified proteins may also serve as immunogens, and hypersensitivity reactions, formation of immune complexes, and delayed hypersensitivities may be the consequences of protein adduct formation. Indeed, many drug- and chemical-related hypersensitivity reactions observed in clinical medicine are based on the formation of covalent protein adducts and their recognition as “foreign” by the immune system [99].

Oxidative stress produces mixed disulfides of proteins with low molecular mass thiols such as glutathione and thus alters protein structure and function. In addition, oxidants and radicals promote the oxidation of amino acids in proteins, which may increase the susceptibility of these proteins to proteolysis [100, 101]. Increased protein oxidation has been implicated in cellular aging and in the mechanisms of toxicity of several redox-active transition metals.

Radicals formed during the biotransformation of xenobiotics may abstract hydrogen atoms from cellular components [82]. The abstraction of hydrogen atoms from polyunsaturated fatty acids of lipids results in a process termed lipid peroxidation. The fatty acid radicals thus formed may react with molecular oxygen to give peroxy radicals and further to hydroperoxides. The initiated radical chain reactions cause the cleavage of carbon–carbon bonds in the fatty acids to short fragments such as α, β-unsaturated carbonyl compounds [102, 103] (see Section Binding of Xenobiotics or their Metabolites to Cellular Proteins).

The disruption of membranes and the formation of toxic hydroperoxides and α, β-unsaturated carbonyl compounds may cause disruptions in cellular calcium homeostasis and thus cause biochemical changes that ultimately lead to cell death [104, 105]. The reaction of electrophilic metabolites with DNA constituents results in the formation of altered purine and pyrimidine bases or other DNA damage such as DNA strand breaks or loss of single bases from the double helix. Many of these modifications are “premutagenic lesions”. After gene expression, these lesions may be translated into mutations [106]. Mutations in certain genes are considered to be the basis for the evolution of neoplastic cells and cancer and thus play a major role in chemical carcinogenesis. Other types of DNA damage may result in the activation of genes important for cellular differentiation or other regulatory functions. Electrophilic intermediates alkylate the nitrogen and oxygen atoms of the purine and pyrimidine bases in DNA; deoxyguanosine is often preferentially alkylated. The site of alkylation of a certain base in DNA is again dependent on the electrophilicity of the alkylation agent; hard electrophiles preferentially react with the oxygen atoms of guanosine, while soft electrophiles alkylate the exocyclic amino groups (Fig. 36).

Figure 36. Regioselectivity of DNA alkylation by different electrophiles

The pattern of base alkylation is different when DNA is modified in biological systems or when isolated DNA, nucleosides, and nucleotides are treated with the xenobiotic or its metabolite(s). Regioselectivity is further modified by solvents, buffer salts, and concentration of reactants. Certain modifications of deoxyguanosine result in the labilization of the glycosidic bond; loss of the deoxyguanosine derivate results in an “apurinic site” in DNA other chemical modifications may result in labilization of the five-membered ring and ring opening after reaction with water (Fig. 37).

Figure 37. Labilization of the bond of guanosine to the DNA backbone by alkylation of the N-7 position resulting in the loss of the modified guanosine from DNA and the formation of an apurinic site (AP)

Figure 38. Ring opening of guanosine in DNA by alkylation of the N-7 position

Radicals formed as reactive intermediates may also cause DNA damage. Besides DNA strand breaks, which have been frequently observed, the reaction of oxygen-derived radicals may also result in the oxidation of purine and pyrimidine nucleotides. Due to the development of sensitive techniques for the characterisation of oxidative modifications in DNA, a number of modified bases have been identified:

8-Hydroxydeoxyguanosine
(7,8-Dihydro-8-oxodeoxyguanosine)

Formamidopyrimidine-deoxyguanosine

Formamidopyrimidine-deoxyadenosine

R,R′ = H, OH, OOH
dR = Deoxyribose

5,6-Dihydrodeoxycytidine

8-Hydroxydeoxyguanosine, a premutagenic modification, is considered as one of the more important lesions induced by oxidative DNA damage; because sensitive methods are available for its quantification, it can serve as a marker for the extent of oxidative DNA modification caused by a xenobiotic or by other processes. DNA oxidation has also been implicated in aging; an increase in oxidative DNA modifications may occur with age due the decreased availability of antioxidants in cells of aging mammals. Several theories suggest a correlation between increased oxidative DNA damage and the increased incidence of tumors in the aged population [107, 108].

2.5.7. *Factors Modifying Biotransformation and Bioactivation*

The biotransformation of xenobiotics may be modified by a variety of factors both intrinsic and extrinsic to the normal functioning of the organism. The changes in the extent of biotransformation may have profound effects on the toxicity of a specific chemical. When biotransformation results in detoxication and rapid excretion, increased rates of biotransformation will decrease toxicity. On the other hand, the toxicity of a chemical bioactivated to reactive intermediates will increase on enhancing biotransformation. A great variety of factors have been shown to influence the extent of biotransformation; many of the effects listed below have been primarily decribed in experimental animals. However, observations in humans (e.g,. after drug treatment) indicate that similar effects, albeit not of the same magnitude or duration, must occur in humans.

2.5.7.1. *Host Factors Affecting Biotransformation*

Enzyme Induction. The activity of biotransformation enzymes can be enhanced by pretreatment with a range of structurally different chemicals. These chemicals can be drugs, pesticides, natural products, environmental contaminants, and even ethanol. The enhanced enzyme activities and the increased enzyme concentrations may results from increased de novo synthesis of the protein, reduced degradation, or from other, often unknown effects. An increase in the concentration of an biotransformation enzyme in the organism, a certain organ or cell type is termed “enzyme induction” [109, 110]. Several hundred different chemicals have been demonstrated to increase the biotransformation of other xenobiotics and to act as enzyme inducers. The majority of these studies focused on the induction of microsomal monooxygenases, mainly cytochrome P450 enzymes; however, other membrane bound enzymes such as UDP-glucuronyl transferases may also be induced. Glutathione *S*-transferases are the only cytosolic biotransformation enzymes whose activities may be increased by the administration of inducers to experimental animals (Table 17).

Table 17. Inducers of the enzymes of biotransformation and enzymes whose cellular concentrations are increased by pretreatment

Inducing agent	Induced enzymes
2,3,7,8-Tetrachlorodibenzodioxin	cytochrome P450, UDPglucuronyltransferase
Ethanol	cytochrome P450
Phenobarbital	cytochrome P450, epoxide hydrolase, UDP-glucuronyltransferases
trans-Stilbenoxide	epoxide hydrolase
3-Methylcholanthrene	cytochrome P450, UDPglucuronyltransferases

The onset, magnitude, and duration of increases in the concentration of biotransformation enzymes after the administration of an inducer and the associated biochemical and morphological effects depend on the chemical nature of the inducing agent, dose, and time of administration. For example, the time required for maximum induction of specific cytochrome P450 enzymes by the classical inducers phenobarbital and 3-methylcholanthrene are different. Moreover, besides increases in the activity of hepatic monooxygenases, phenobarbital administration results in marked hepatic hypertrophy and proliferation of the smooth endoplasmatic reticulum; these effects are absent in animals treated with 3-methylcholanthren. Induction by parenteral application of 3-methylcholanthren results in maximum enzyme concentrations in the liver within 48 h, whereas maximal induction by parenteral application of hypnotic doses of phenobarbital requires up to 5 d.

Enzyme induction is reversible after withdrawal of the inducing agent, and the enzyme activities return to basal levels over a characteristic time span. Again, this time span is dependent on the chemical nature of the inducing agent. For example, cessation of phenobarbital treatment will result in a decline of enzyme activities to basal levels within one to two weeks. The mechanisms of enzyme induction are complicated and only partially understood. Apparently, different chemicals influence the activities of the biotransformation enzymes by different mechanims; even the effect of a specific chemical on different enzymes may be due to separate mechanisms (Table 18) [111].

Table 18. Mechanisms of cytochrome P450 enzyme induction by different xenobiotics

Cytochrome P450	Inducing agent	Mechanism of induction
1A1	2,3,7,8-tetrachlorodibenzodioxin	increased gene transcription
1A2	3-methylcholanthrene	stabilization of messenger RNA
2B1, 2B2	phenobarbital	increased gene transcription
2E1	ethanol, acetone	protein stabilization
3A1	dexamethasone	increased gene transcription, independent of glucocorticoid receptor
3A1	triacetyloleandomycin	protein stabilization
4A1	clofibrate	increased gene transcription, receptor mediated

Only a few mechanisms are well understood. Modulation of gene expression seems to be the basis for many inductive effects. For example, induction of cytochrome P450 1A1 is prevented by inhibitors of protein synthesis. Moreover, studies using the potent inducing agent 2,3,7,8-tetrachlorodibenzodioxin identified a high-affinity binding protein with the properties of a receptor for 2,3,7,8-tetrachlorodibenzodioxin in rat liver cytosol [112, 113]. Binding of 2,3,7,8-tetrachlorodibenzodioxin to this protein results, after further interaction with other proteins, in the translocation of the formed complex from the cytosol to the nucleus. This translocation is followed by interaction with specific recognition sites on the genome, transcription, and translation of the specific gene for cytochrome P450 1A1 and for other biotransformation enzymes such as UDP-glucuronyl transferases (Fig. 39).

Figure 39. The Ah receptor (Ah-R) and mechanism of enzyme induction by 2,3,7,8-tetrachlorodibenzodioxin (T)

In contrast, the mechanisms of enzyme induction by phenobarbital and, for example, ethanol are not defined. A specific receptor for phenobarbital could not be demonstrated, but some experiments suggest involvement of the glucocorticoid receptor in phenobarbital-mediated enzyme induction. Ethanol and other inducers seem to stabilize the cytochrome P450 2E1 protein against degradation by an unknown mechanism.

Enzyme Inhibition. The decrease in the activity of specific biotransformation enzymes is termed inhibition of biotransformation. As noted above, inhibition of biotransformation may increase or decrease the toxicity of a xenobiotic. For example, the inhibition of cytochrome P450 by 2-(diethylamino)ethyl-2,2-diphenylpentanoate (SKF-525A) causes an increase in hexobarbital sleeping time, but a decrease in the hepatoxicity of carbon tetrachloride.

Several mechanisms responsible for inhibition of xenobiotic metabolizing enzymes are operative [114, 115]. Besides inhibition of protein synthesis and thus synthesis of the enzyme, xenobiotics may irreversibly bind to the active site of the enzyme. This process is termed suicide inhibition [116]. Following activation of the xenobiotic by the enzyme, the reactive intermediate formed reacts with constituents of the enzyme at or near the active site, thus blocking further catalytic activity. This effect has been demonstrated with several xenobiotics which are inhibitors of cytochrome P450, such as alkenes and compounds containing allylic and acetylenic derivatives. For example, ethylene oxide, the reactive metabolite formed by cytochrome P450 catalyzed oxidation of ethylene, may alkylate the pyrrole nitrogen atoms in the heme moiety and thus result in heme destruction.

During exposures to mixtures, chemicals with high affinity to certain biotransformation enzymes will be preferentially metabolized, and thus the biotransformation of other constituents of the mixture will be reduced or even totally inhibited. This reduced biotransformation may also alter the toxicity of a chemical present in a mixture compared with that of the pure chemical. For example, coadministration of ethanol markedly reduces the toxic effects of methanol (metabolic acidosis, reversible or even permanent blindness). These toxic effects are caused by the oxidation of methanol to formic acid as toxic metabolite; formic acid accumulates in the organism and damages the optical nerve. Oxidation of methanol to formaldehyde is competitively blocked by administration of ethanol; under these circumstances, the toxic metabolite formic acid can not be formed; methanol is excreted from the organism unchanged in the urine and by exhalation.

Inhibition of some biotransformation enzymes may also be caused by effects on the tissue levels of necessary cofactors. The availability of glutathione for conjugation is reduced by blocking glutathione biosynthesis; diethyl maleate and some other chemicals deplete intracellular glutathione concentrations by reacting with glutathione to give a glutathione *S*-conjugate. Pretreatment of experimental animals with these chemicals followed by the application of a xenobiotic which requires glutathione for detoxication will result in an increased toxic response. Moreover, large doses of nontoxic chemicals metabolized by sulfotransferases may deplete the cofactor for sulfate conjugation and may thus alter the disposition and, probably the toxicity, of other xenobiotics that undergo sulfate conjugation.

Genetic Differences in the Expression of Xenobiotic Metabolizing Enzymes. The ability of different animal species to metabolize xenobiotics is related to evolutionary development and therefore to different genetic constitution; thus, major species differences in the extent and pathways of biotransformation exist. These variations may be divided into qualitative and quantitative differences. Qualitative differences involve metabolic pathways and are related to species defects or peculiar reactions of a species. For example, guinea pigs do not have the enzymatic capacity to catalyze the last step in mercapturic acid formation, the *N*-acetylation of cysteine *S*-conjugates, and therefore excrete cysteine *S*-conjugates as end products of this pathway. Certain species such as cats do not have the capability to form glucuronides from xenobiotics.

Quantitative variations are often due to species differences in gene and enzyme regulation. For example, interindividual differences have been decribed in humans in the biotransformation of many drugs. The *N*-acetylation of the tuberculostaticum Isoniazid has a genetic basis. Some individuals are homozygous for a recessive gene, and this may result in the absence of isoniazid *N*-acetyltransferase, that is, they are “slow acetylators”. In normal homozygotes or heterozygotes, “rapid acetylators”, Isoniazid is rapidly transformed to the *N*-acetyl derivative. The *N*-acetyltransferase polymorphisms are correlated with different responses to Isoniazid-induced toxicities. This genetic polymorphism is also seen in human, 80% of the Japanese and Eskimos are “rapid acetylators”; whereas in some European populations only 40 to 60% are “rapid acetylators” [117]. Polymorphisms in the expression of cytochrome P450 1A1 and a specific glutathione *S*-transferase in human

lung have been implicated in an increased rate of lung cancer in individuals expressing high cytochrome P450 1A1 and deficient in this glutathione *S*-tansferase. Cytochrome P450 1A1 bioactivates aromatic hydrocarbons present in cigarette smoke to yield electrophiles; glutathione *S*-transferase detoxifies these metabolites.

Influence of sex on biotransformation reactions. Sex differences in the extent and pathways of biotransformation may be based on sex-dependent expression of certain biotransformation enzymes. For example, adult male rats metabolize many xenobiotics at higher rates than females; both phase-I and phase-II biotransformation reactions seem to be influenced by sex-dependent factors. With cytochrome P450, at least three different hepatic enzymes have been demonstrated to be under the control of sex-hormones (Table 19).

Table 19. Sex hormone-dependent hepatic cytochrome P450 in the rat

Enzyme	Sex specificity	Remarks
P450 2D	female	expressed at a hormone-independent basal rate, stimulated by estrogen, suppressed by androgen
P450 2C	male	
P450 3A	male	neonatally imprinted by androgen

In addition to the liver, sex differences in biotransformation are also found in extrahepatic tissues such as the kidney and may be responsible for sex-specific toxic effects of xenobiotics in these organs. For example, the kidneys of male mice contain a cytochrome P450 enzyme which bioactivates chloroform, acetaminophen, and 1,1-dichloroethene to reactive intermediates. The enzyme is present only in much lower activity in female mice, which are thus not susceptible to the renal toxicity of these chemicals.

In experimental animals, sex differences in the expression of biotransformation enzymes usually become apparent at puberty and are maintained throughout adult life. Despite the relatively large sex-dependent variations seen in animal studies, sex seems not to have a profound influence on the biotransformation of chemicals in humans.

Dietary constituents and the biotransformation enzymes. Nutritional factors influencing biotransformation may be mineral deficiencies, vitamin deficiencies, protein content, starvation, and natural substances in the diet. Mineral deficiencies (calcium, copper, zinc) have been shown to reduce the activities of cytochromes P450. On the other hand, an excess of dietary iron has been observed to increase monooxygenase activity. Dietary cobalt, calcium, and manganese may increase the hepatic levels of glutathione and may thus influence glutathione *S*-conjugate formation. Several vitamins are directly or indirectly involved in the regulation of cytochrome P450. For example, diets deficient in vitamins C and E reduce the activity of monooxygenases, whereas deficiencies in other vitamins increase monooxygenase activity. Moreover, several vitamins serve as important cellular antioxidants and influence the energy and redox state of the cell and thus also affect biotransformation reactions.

Low-protein diets generally reduce the activity of cytochrome P450 and certain phase-II biotransformation reactions. Thus, the nutrient status may also modify the toxicity of xenobiotics. For example, dimethylnitrosamine is a potent hepatocarcinogen in rats kept on a high-protein diet; but almost without effect in rats kept on a low-protein diet. Food deprivation reduces the hepatic concentration of glutathione by as much as 50% due to reduction of glutathione biosynthesis. Thus, xenobiotics detoxified by glutathione conjugation are more toxic in starved than in fed animals. Fasting has also been shown to increase the levels of cytochrome P450 2E1, but decrease the levels of cytochrome P450 2C11. Several natural ingredients in the diet of laboratory animals such as indoles, diallyl disulfid,e and psoralens may increase the activities of cytochrome P450. However, some of these compounds may selectively increase some cytochrome P450 enzymes, but inhibit others. For example, diallyl disulfide, a constituent of garlic, has been shown to induce cytochrome P450 2B in rats, but inhibits cytochrome P450 2E1. Vegetable ingredients present in broccoli are potent inducers of phase-II biotransformation enzymes and thus increase the capacity of the organism to detoxify reactive intermediates. These natural ingredients are thought to play a major role in the anticarcinogenicity of diets rich in those vegetables.

2.5.7.2. *Chemical-Related Factors that Influence Biotransformation*

Xenobiotic-related factors influencing biotransformation are the physiocochemical properties (i.e., chemical structure including the presence of functional groups) and dose. The major determinant of the rate of biotransformation is the concentration of the substrate at the active site of the enzyme. This concentration is determined by structure and lipophilicity and by dose. Lipophilic xenobiotics readily cross cell membranes and are rapidly absorbed and distributed in the organism. Moreover, lipophilic xenobiotics show a higher partitioning into lipid membranes. These factors contribute to higher concentrations of lipophilic xenobiotics at the active center, especially of membrane-bound enzymes. The presence of functional groups also influences rates and routes of biotransformation. Certain functional groups may compete for the same substrate for conjugation; also, specific functional groups may undergo different reactions, as indicated in Figure 40 for *p*-aminobenzoic acid.

Figure 40. Possible biotransformation pathways for *p*-aminobenzoic acid

The presence of other specific functional groups may have a major effect on biotransformation and its regioselectivity. For example, the presence of trifluoromethyl groups in alkanes renders the adjacent methylene carbon atom almost inert to hydroxylation and strongly influences the regioselectivity of enzymatic hydroxylations on aromatic rings.

Dose is one of the most important factors determining rate and route of biotransformation for more complex molecules. Certain biotransformation enzymes have a high affinity but low capacity for a specific chemical, while others have a high capacity but low affinity. As dose increases, high-affinity, low-capacity enzymes will become staturated, and low-affinity, high capacity pathway(s) will biotransform a larger percentage of dose [118].

2.5.8. ***Elimination of Xenobiotics and their Metabolites***

The evolution of complex forms of life necessitated the development of specialized mechanisms to eliminate waste products formed from endogenous compounds and to prevent the accumulation of toxic xenobiotics present taken up in the diet. Excretion of wastes by the earlier forms of aquatic life was largely passive and involved the loss of large volumes of water and nutrients. For land-living animals, conservation of water, minerals, and nutrients was necessary for survival. Therefore, complex mechanisms for the elimination of both endogenous chemicals and xenobiotics evolved. A wide variety of xenobiotics can be handled by evolved excretory mechanisms and can thus be efficiently eliminated from the body.

Xenobiotics may be excreted as the parent compound, as metabolites, and/or as conjugates formed in phase-II biotransformation reactions. A major route of excretion of xenobiotics is via the kidney, and in some cases the urinary elimination of parent compound or metabolite can be used to determine absorbed dose. The kidney is the only organ which functions almost exclusively as an organ of elimination. The cells of the liver have more varied functions than those found in the kidney; however, the liver also plays an important role in the excretion of chemicals not effectively eliminated by the kidneys. Chemicals may be eliminated from the liver into bile and thus be finally excreted with feces. Active transport mechanisms, that is, transport against a concentration gradient, play a major role in renal and hepatic excretion of xenobiotics. In contrast, in most other organs which may serve as excretory systems for xenobiotics, passive excretion mechanisms are operative. For example, volatile chemicals and metabolites may be eliminated in expired air; this route is quantitatively significant for some solvents and inhalation anesthetics. Specific xenobiotics may also be excreted in sweat, saliva, and milk.

2.5.8.1. *Renal Excretion*

The kidneys are the only organs that are primarily designed for excretion. The function of these organs accounts for the elimination of most of the byproducts of normal metabolism and most of the polar xenobiotics and metabolites of lipophilic xenobiotics to which humans and experimental animals are exposed [119]. The kidney is a complex structure which consist of a number of different cell types [119-121]. Essentially, the kidney filters the bood and all components present in blood with a molecular mass of less than 50 000 (depending on structure and charge) enter the tubular system; there, important nutrients and most of the filtered water are recovered. Only a small fraction of the primary filtrate is excreted as urine (one to two liters per day). The human kidney consists of approximately two million nephrons, which are the functional units that filter the blood and the recover essential nutrients. The structure and components of a single nephron are shown in Figure 41.

Figure 41. Structure of a nephron

a) Glomerulus; b) Renal artery; c) Proximal tubule; d) Renal vein; e) Loop of Henle; f) Distal tubule; g) Collecting duct

Glomerular Filtration. Renal excretion is the product of three complex and interactive processes: glomerular filtration, tubular reabsorption, and tubular secretion. Glomerular filtration is the passive filtering of the plasma as a result of its passage through glomerular pores (7–10 nm in diameter) under hydrostatic pressure generated by the heart. The average rate of glomerular filtration in adults is 125 ml/min or almost 200 liters/d. Glomerular filtration shows little specificity other than molecular size, and free solutes in the plasma that pass through the glomerular pores will all appear in the filtrate. Only protein-bound low molecular mass xenobiotics will not appear in the filtrate and remain in blood. Glomerular filtration is influenced by factors that affect the hydrostatic pressure or integrity of the glomerulus; thus, these factors may result in elevated plasma concentrations of excretory products formed from endogenous chemicals and from xenobiotics.

Tubular Reabsorption. The daily volume of glomerular filtrate exceeds that of the total body water by a factor of four and contains many necessary nutrients such as glucose, amino acids, and salt; therefore, most of the glomerular filtrate must be recovered. Thus, the second major process occuring in the kidney is tubular reabsorption. A number of discrete mechanisms, both active and passive and of varying degrees of specificity, are involved in tubular reabsorption. Many of these reabsorptive mechanisms are located in the cells of the proximal segments of the tubules. These cells account for the reabsorption of 65–90% of the glomerular filtrate. Glucose, certain cations, low molecular mass proteins, amino acids, and organic acids are actively reabsorbed. Water and chloride are passively reabsorbed as a result of the osmotic and electrochemical gradients generated by the active transport of sodium and potassium. The osmolarity of the fluid in the collecting duct is regulated in the loops of Henle; most of the remaining water and ions are reabsorbed in the distal tubules and collecting ducts. The rate of reabsorption in these segments of the proximal tubule is regulated to maintain the osmolar concentration of the blood. Most xenobiotics are also reabsorbed after glomerular filtration by passive diffusion during passage through the nephron. Passive tubular reabsorption of lipophilic xenobiotics is therefore greater than the reabsorption of polar xenobiotics or endogenous wastes.

Tubular Secretion. Xenobiotics present in blood may also be excreted by the kidney by tubular secretion. This secretion transports xenobiotics from the peritubular fluid (blood) to the lumen (urine) in the tubule. Tubular secretion is often selective; active transport mechanisms account for the secretion of many organic acids, including glucuronides and sulfates, and strong organic bases.

The secretion of weak bases and some weak acids may also occur by a passive mechanism that utilizes pH differences between peritubular fluid and urine. At the pH of the tubular lumen, these compounds become ionized and do not diffuse back across the cell wall.

Factors Affecting Renal Excretion of Xenobiotics. Xenobiotics are excreted by the same mechanisms which eliminate endogenous wastes; highly polar xenobiotics in plasma water are removed primarily by glomerular filtration and excreted in the urine with minimal involvement of tubular reabsorption or secretion. The rate of renal elimination of most of these xenobiotics is largely dependent on the rate of glomerular filtration. Since lipophilic compounds cross cell membranes more readily, they distribute into a much larger tissue volume than polar compounds, which are more likely to be restricted to the vascular volume. However, lipophilic xenobiotics metabolized to more polar compounds are usually rapidly returned to the circulation and are readily excreted. Therefore, the rate of metabolism of a xenobiotic may also play an important role in its rate of excretion.

2.5.8.2. *Hepatic Excretion*

Nutrients and xenobiotics are delivered from the gastrointestinal tract to the liver by the portal vein to be biotransformed there. Thus the liver is located between the intestinal tract and the general circulation and ideally located for the biotransformation of nutrients and xenobiotics taken up by this route. Besides participating in the biotransformation of xenobiotics, the liver is a major excretory organ and contributes to the excretion of many xenobiotics by eliminating them with bile into the gut and thus into feces [122-125].

The bulk of the liver consists of cells arranged in plates two cells thick. These plates are arranged radially around the terminal branches of the hepatic veins and are exposed to blood from the portal vein and hepatic artery flowing through interconnecting spaces referred to as hepatic sinusoids. The sinusoidal walls are freely permeable even to relatively large particles; special transport may only play a role in the uptake of certain anions from the blood. The epithelial hepatic cell is the smallest unit of the liver and accounts for most of the varied functions of this organ, including storage, secretion, biotransformation, and excretion (Fig. 42).

Figure 42. One-compartment model with first-order elimination and instantaneous absorption

Bile formation is thought to be the result of active transport of certain ionized compounds and passive transport of other solutes and water, which follow a concentration or electrochemical gradient. Active secretion of anions and cations appears to be controlled by different mechanisms, but the compounds actively excreted are usually amphipathic molecules and have both polar and nonpolar portions in their structures. Bile acids are the classical example of endogenous amphipathic molecules. Conjugates of lipophilic xenobiotics are also examples of amphipathic molecules, and many of these conjugates are ionized, a fact that facilitates excretion from the hepatocyte by active transport mechanisms.

As a result of both active and passive secretion into the bile, xenobiotics excreted into bile may be classified into different groups. Solutes found in bile may be divided according to their concentration in bile versus blood. For example, the excretion of Na^+, K^+, Cl^-, and glucose, for which the bile/blood ratio is close to unity, is thought to be passive. Conjugates of xenobiotics and bile acids have a bile/blood ratio of greater than 10 and are thought to be actively excreted from liver into bile. Other compounds such as proteins, inulin, sucrose, and phosphates do not cross the canalicular membrane of hepatocytes and have a bile/blood ratio of much less than one. Bile secreted by the liver cells into the bile canaliculi flows into the narrowest branches of the bile duct, the cholangioles, then into the hepatic duct, which carries the bile to the gallbladder and finally into the intestine. Lipophilic xenobiotics may appear in bile at low concentrations prior to metabolism. However, a compound absorbed from the stomach or intestine after ingestion is likely reabsorbed from the intestine if it is secreted in bile prior to structural modifications by biotransformation. Moreover, conjugates excreted into bile, such as glucuronides, may be hydrolyzed by enzymes present in the bacteria of the intestinal microflora, and the aglycone may be reabsorbed. Most xenobiotics reabsorbed from the intestine are returned to the liver. The process of excretion into bile, reabsorption from the intestine, and return to the liver is termed enterohepatic circulation. Enterohepatic circulation serves as an efficient physiological recovery mechanism for bile acids and certain hormones. When xenobiotics are trapped in this cycle, their rate of excretion from the body may be significantly reduced and their toxicity may be significantly increased.

Effect of Molecular Mass on Hepatic Excretion of Xenobiotics. From the liver cell, xenobiotics may be excreted into bile or returned to blood. The molecular mass of nonvolatile organic xenobiotics or their metabolites determines the primary route by which they are excreted from the hepatocyte. In the rat, xenobiotics, their metabolites and conjugates formed in phase-II reactions with molecular masses greater than 500 are most often excreted into bile, while xenobiotics and their metabolites with molecular masses of less than 350 return from the hepatocyte to blood and are thus delivered to the general circulation and to the kidney for excretion. In humans, the critical molecular mass threshold for biliary excretion is approximately 500.

2.5.8.3. *Xenobiotic Elimination by the Lungs*

Any xenobiotic present in blood with sufficient volatility will pass from the blood across the alveolar membrane into the air space of the lung and may be exhaled. The rate of elimination from blood of a volatile xenobiotic is dependent on the solubility of the xenobiotic in blood, the rate of respiration, and the blood flow to the lung. Xenobiotics like diethyl ether, which are highly soluble in blood, are rapidly eliminated by exhalation; their elimination may also be efficiently increased by a forced increase in the rate of respiration (hyperventilation). In contrast, volatile xenobiotics with low solubility in blood are only slowly cleared from the lung and thus from the body by exhalation, and their rate of exhalation may not be markedly influenced by hyperventilation. The proportionality among xenobiotic volatility, blood solubility, and the concentration of a volatile xenobiotic in the blood is utilized to quantitate blood alcohol content and thus estimate sobriety by breath analysis.

2.6. Toxicokinetics

The toxic response to chemical exposure depends particularly on the magnitude, duration, frequency, and route of exposure. These determine the amount of material to which an organism is exposed (the exposure dose) and hence the amount of material which can be absorbed (the absorbed dose). The latter determines the amount of material available for distribution and toxic metabolite formation, and hence the likelihood of inducing a toxic effect. Absorption and metabolite accumulation are opposed by elimination. All these factors define the disposition of the xenobiotic. The modeling and mathematical description of the course of disposition of a potentially toxic xenobiotic in the organism with time is termed toxicokinetics. Most of the methodologies and principles applied in toxicokinetics were first used to model the kinetics of chemicals applied as drugs (pharmacokinetics).

The goal of both toxicokinetics and pharmacokinetics is to quantitate the dynamic course of xenobiotic absorption, distribution, biotransformation, and elimination processes in living organisms with time. Both the whole process of disposition or individual steps such as elimination may be characterized.

2.6.1. *Pharmacokinetic Models*

A pharmacokinetic or toxicokinetic model is a functional representation that has the ability to describe the movement of a xenobiotic over time in a real biological system [126-128]. A common way to describe the kinetics of drugs is to represent the body as a number of interconnected compartments which may or may not have an anatomical or physiological reality. These compartments represent all tissues, organs, and fluids in the body that are kinetically indistinguishable from each other. A compartment might be represented by a cluster of cells within an organ, an organ, the blood, or the whole body taken together. More recently, so called physiologically based pharmacokinetic and toxicokinetic models have been developed. These models permit the modeling of the time course of the concentration of a chemical in a tissue on the basis of physiological considerations and may be particulary useful in interspecies extrapolations such as are necessary in risk assessment.

2.6.1.1. *One-Compartment Model*

This simplest toxicokinetic model depicts the body as a single homogeneous unit within which a xenobiotic is uniformly distributed at all times. The toxicokinetics of a xenobiotic may be analyzed by a one-compartment model if the determined plasma concentration after a single dose decreases exponentially (Fig. 43; the plot of the logarithm of the plasma concentration versus time yields a straight line). In this model, elimination of a chemical from the body occurs by first-order processes. A mathematical description of the first-order process is

$$\frac{dX}{dt} = -k_e X$$

where X is the amount in the body at time t and k_e is the rate constant for first-order elimination. In compartmental analysis, k_e is often referred to as an apparent first-order rate constant, to emphasize that the underlying processes may in reality only approximate first-order kinetics. For example, the xenobiotic might actually be eliminated by active biliary secretion, for which zero-order saturation kinetics would be observed under suitable conditions.

Figure 43. Structure of a liver cell (hepatocyte) and possible pathways for the uptake and elimination of xenobiotics and their metabolites

a) Space of Disse; b) Nucleus; c) Bile; d) Liver capillary; e) Sinusoidal wall; f) Rough endoplasmic reticulum; g) Smooth endoplasmic reticulum; h) Mitochondria; i) Golgy complex; j) Bile duct

If the xenobiotic is not present in the organism and a known amount X_0 is rapidly administered, the total amount of the xenobiotic initially in the body will be approximately X_0 = total dose. The amount of the xenobiotic present in the organism at a certain time after administration is then

$$X(t) = X_0 \times e^{-kt}$$

The first-order rate constant of elimination can be determined from the slope of the plot of the logarithmic plasma concentration versus time and can be used to estimate the half-life of elimination for the xenobiotic:

$$t_{1/2} = \frac{0.693}{k_e}$$

Within seven half-lives, a xenobiotic is almost completely eliminated (99.2%), although theoretically complete elimination will never be achieved. Important characteristics of the first-order elimination of a xenobiotic according to the one-compartment model are:

1. The half-life of the xenobiotic is independent of dose; the semilogarithmic plot of the plasma concentration of the xenobiotic versus time yields a straight line.
2. The concentration of the xenobiotic in plasma decreases by a constant fraction per time unit.

Xenobiotics responsible for toxic effects are usually not injected into blood and intake is thus not instantaneous compared to distribution and elimination and a lag period before maximal concentration in plasma is observed. If intake also approximates a first-order absorption process, then the rates of absorption and elimination will determine the time course of the plasma concentration (Fig. 44).

Figure 44. One- compartment model with first-order absorption and first-order elimination

The rate of change in the concentration of a xenobiotic in a one-compartment model with first-order absorption and elimination may be described by:

$$\frac{dX}{dt} = -k_e X_e + k_a X_a$$

where k_a is the rate constant of absorption, X_a is the amount of the xenobiotic present at the site of absorption, and k_e is the rate constant of elimination.

The rate constant of elimination can be experimentally determined by treating the elimination phase as if it occurred after the intravenous injection described above by extrapolation of the terminal straight line of the semilogarithmic plot to the ordinate at a putative X_0. By determing the plasma concentration of the xenobiotic at time points shortly after administration, the rate constant for absorption can be determined by plotting the difference between the early plasma concentrations and the extrapolated portion of the elimination curve.

2.6.1.2. *Two-Compartment Model*

If a xenobiotic does not distribute and equilibrate throughout the body rapidly, a two-compartment model provides a better description of the kinetics of disposition. In this case, the semilogarithmic plot of plasma concentration versus time does not yield a straight line. In two-compartment models, the main or central compartment is assumed to represent the blood and highly perfused organs and tissues such as the liver, the heart, and the kidneys, which are in rapid distribution equilibrium with the blood, while the second or peripheral compartment corresponds to poorly perfused tissues such as muscles and fat. This model is depicted in Figure 45 and is called a two-compartment open pharmacokinetic model.

Figure 45. Two-compartment model for the distribution of a xenobiotic

X_c = concentration in the central compartment; X_p = concentration in the peripheral compartment; X_0 = initial dose; k_{21}, k_{12}, k_{10} = rate constants

The time course of the plasma concentration of the xenobiotic can be decribed by two overlying monoexponential terms of the type:

$$X = Ae^{-kt} + Be^{-k't}$$

where *A* and *B* are proportionality constants and *k* and *k′* are rate constants. Thus, the pharmacokinetics of a two-compartment model describe a biexponential decay in the amount of xenobiotic in the body. Analogous to a one-compartment model, a distribution equilibrium is assumed to exist within each compartment that can be expressed in terms of blood concentration. According to this equation, a plot of the logarithm of blood concentration versus time will yield a biphasic decay from which the constants *A*, *B*, *k*, and *k′* can be estimated either graphically or by nonlinear regression analysis. Once these experimental constants have been determined, the pharmacokinetic parameters can be calculated. The numerical values of these parameters can aid in assessing the relative importance of tissue distribution and elimination to the disposition of the xenobiotic.

2.6.2. *Physiologically Based Pharmacokinetic Models*

Although compartmental analysis models are convenient to use and provide useful descriptions of the overall time course of xenobiotic disposition, the practical limitations of curve fitting to experimental data generally restrict such models to one or two compartments. Alternatively, it is often possible to develop a compartmental model from physiological principles and thereby circumvent the inherent limitations of curve-fitting analysis. A physiological pharmacokinetic or toxicokinetic model is a mathematical description of the disposition of a xenobiotic in the organisms or in a part thereof (e.g., a specific organ) Such a model is constructed by using physiological and biochemical parameters such as blood flow rates, tissue and organ sizes, binding, and biotransformation rates [129-131]. These are generally more complex and require the specification of many parameters; thus, physiological compartmental models are still simplified representations of biological systems. In addition, the accurate determination of physical and biochemical parameters is often both difficult and inaccurate. However, the physiological framework provides several advantages: the physical definition of compartments and transfer rates facilitates the incorporation of existing knowledge about the quantitative behavior of biological systems into the model; physiological changes with time during chronic exposure to a xenobiotic, such as those due to physical growth, or induction of biotransformation and changes in excretion rates, can be introduced (Fig. 46).

Figure 46. Schematic representation of a physiologically based toxicokinetic model

Most important, however, a reasonable basis exists for extrapolating the kinetics of a xenobiotic to predict the disposition of a xenobiotic following various types and patterns of exposure, and to extrapolate from experimental data obtained in one species of experimental animals to other animal species and humans.

Physiology-based models use the concepts of mass balance and flow-limited transport under the following definitions: Blood serves to distribute a xenobiotic from the site of absorption to the other parts of the body. In the normal sequence of events, a chemical entering the bloodstream is often rapidly distributed within the blood, and its blood concentration can be considered to be essentially uniform.

The chemical enters and leaves the compartment with the blood flow and diffuses or is transported from blood to tissue and back. The chemical may also undergo a variety of physical interactions, such as binding to macromolecules, and the result is a partitioning between tissue and blood that depends on the affinity of the chemical for each medium. Diffusion or transport directly between adjacent compartments, enzymatic biotransformations, and excretion may also occur. The net result of all of these changes is expressed by a mass-balance differential equation, which is simply a mathematical statement of the conservation of mass. Frequently, these mass balance equations can be greatly simplified, since many of the terms required may not apply to a particular compartment.

[Top of Page]

3. Mechanisms of Acute and Chronic Toxicity and Mechanisms of Chemical Carcinogenesis

3.1. Biochemical Basis of Toxicology

Since the 1960s, toxicology has moved from observing and classifying the harmful effects of chemicals in animals with the tools of pathology (descriptive toxicology), to a discipline able to explain the mechanisms of the basic changes in cell function responsible for toxic effects (mechanistic toxicology). This progress resulted from the widespread application of techniques and concepts from a range of basic sciences, most notably biochemistry and cell biology. Mechanistic explanations of toxic phenomena aid in the prevention of chemical or biological toxicity and provide a rational basis for the use of animal data to assess the anticipated consequences of human exposure to a particular chemical.

Many toxic compounds are chemically stable and produce their characteristic effects by interference with biochemical or physiological homeostatic mechanisms. Many adverse events are the consequence of disturbance of normal physiology and do not result in cell death. A xenobiotic may, for example, activate plasma membrane receptors and induce physiological signal transduction pathways. Induction of a normal cascade at the wrong time or to the wrong extent (too much) may cause undesirable or harmful effects. Toxic compounds interfering with homeostatic mechanisms do not necessarily cause cell death; however, the induced changes may have a harmful impact both on the altered cells and on the involved tissue or on the entire organ. Therefore, it is critical to have a proper knowledge on biochemical and molecular sites of action of the xenobiotics.

Cytotoxicity resulting in cell death is often the consequence of exposure to a harmful xenobiotic, but the number of cells which must be killed before the function of a tissue or organism is noticeably impaired is highly variable. Some cell types like the epithelia of the kidney and the liver have the ability to regenerate in response to damage, while others like neurons can not. Furthermore, some organs, such as the liver, lung, and kidney, have a substantial functional reserve capacity in excess of normal requirements, and normal function can be maintained even in the presence of extended necrosis.

In addition to cell death, disturbances in the regulation of cell division induced by toxic xenobiotics may have harmful long-term consequences for the organism affected. Nonlethal alterations in the genome of somatic cells can result in mutations and can lead to malignant transformation and tumor formation [132]. More recently, it has become clear that compounds not directly interacting with the genomic DNA can also produce cancer by so-called epigenetic mechanisms [133]. These may involve a proliferative response of epithelial cells to cytotoxicity, as is suggested to occur with high-dose carcinogens such as allyl isothiocyanate and chloroform, or a more direct action that enhances the rate of cell division in the absence of cytotoxicity, as is seen with 2,3,7,8-tetrachlorodibenzodioxin. Increased cell replication, whatever the cause, is accompanied by increased chance of unrepaired DNA lesions that may be fixed as mutations. Hyperplasia has long been suspected of preceding neoplasia, but the inevitability of such a progression has never been established on a pathological basis alone. Even in absence of foreign compounds, DNA is damaged to a considerable extent by reactive oxygen species formed during different biochemical processes in the cell, it may thus be speculated that nongenotoxic carcinogens act by enhancing the likelihood of this normal DNA damage being fixed as a mutation and leading to cancer [134].

Having established the fundamental differences between toxic chemicals which act through physiological inbalance, through cytotoxicity, or by causing alterations in cell proliferation, we now consider some sites or chemical reaction mechanisms of toxic action. The following major mechanisms are neither comprehensive nor mutually exclusive.

3.2. Receptor-Ligand Interactions

3.2.1. *Basic Interactions*

Some xenobiotics can interact with physiological receptors due to structural similarities to endogenous compounds. The toxic effects of these chemicals are related to

their ability to interfere with normal receptor–ligand interactions either as agonists or as antagonists of the physiological ligand. Receptors are macromolecular components, most often proteins, of tissues which interact with specific endogenous ligands or structurally related xenobiotics to induce a cascade of biochemical events and produce characteristic biological effects. The binding between a receptor (R) and a ligand (L) is usually reversible and can be described by the equilibrium reaction:

$$R + L \underset{k_2}{\overset{k_1}{\rightleftharpoons}} RL$$

The dissociation constant K_d that describes this relationship is thus given by:

$$K_d = \frac{k_1}{k_2} = \frac{[L][R]}{[LR]}$$

where [L], [R], and [LR] are the concentrations of ligand, unbound receptor, and ligand-bound receptor, respectively. The affinity of the ligand to a certain receptor is proportional to $1/K_d$. The ligand may be an endogenous substance that interacts with the receptor to produce a normal physiological response, or it may be a xenobiotic that may either elicit (agonist) or block (antagonist) the response.

Receptor–ligand interactions are generally highly stereospecific. Usually, small changes in the chemical structure of the ligand can Drastically influence its capability to bind to the receptor and thus reduce or completely abolish the effect elicited by the ligand–receptor interaction. In other cases, changes in the chemical structure may have an important impact on the response without altering the binding of the xenobiotic to the relevant receptor. Differences in the extent of activity are not only observed with structurally distinct chemicals but also with chemicals that are chiral and thus may be present as racemic mixtures of stereoisomers. Synthetic chemicals with chiral centers generally contain both enantiomers, often in a 1:1 ratio, yet in many instances only one of the enantiomers is biologically active. In pharmacological or toxicological studies, the inactive or weakly active enantiomer should be viewed as an “impurity” which may confound the interpretation of results obtained with the racemic mixture. Because the enzymes responsible for biotransformation of xenobiotics also contain active sites with specific steric requirements, stereoisomers may be differentially biotransformed. The selective biotransformation of only one enantiomer may markedly alter the potency and efficacy of one enantiomer compared with another. Stereoselective differences in action among enantiomers should not be surprising, if one considers that these chemicals are mirror images, much as the right hand is of the left, and that receptors have a physical orientation that can be compared with a glove. Although the left-hand and right-hand gloves look remarkably similar, they do not fit both hands equally well. However, these theoretical considerations do not imply that stereoisomers always elicit different responses. Since the chiral center of a stereoisomer is not necessarily involved with the active site of the receptor, chirality does not always results in differences in toxic response among enantiomers.

The acute toxic effects of many xenobiotics are related directly to their ability to interfere with normal receptor–ligand interactions. This is most clearly the case with neurotoxins, acting within and outside the central nervous system (CNS). The proper function of the nervous system is highly dependent on a diverse array of receptor–ligand interactions. For example, the belladonna alkaloids atropine and scopolamine bind to and block the cholinergic receptors, the binding site of the physiological agonist acetylcholine (Fig. 47). The interactions of acetylcholine and atropine are an excellent example demonstrating that interference of a xenobiotic with physiological regulatory mechanisms may result both in desired (pharmacological) and an undesired (toxic) effects.

Figure 47. Induction of physiological response(s) by binding of the agonist acetylcholine to postsynaptic receptors; in contrast, binding of the antagonist atropine to the same receptors does not induce biological effects

Since atropine itself can not elicit the physiological responses mediated by acetylcholine binding to this receptor, toxic effects may result. In clinical therapy, atropine is often used as an antispasmodic to reduce the hypermotile state of the gastrointestinal tract or the urinary bladder. Its anticholinergic effects are also utilized in cardiovascular pharmacology to decrease pathologically elevated heart rates. At the same time, however, blockage of acetylcholine-mediated physiological cascades may cause dry mouth, blurred vision, and constipation. In addition, in the CNS toxic effects of atropine include restlessness, confusion, hallucinations, and delirium. Blockage of the receptors for the neutral amino acid glycine by strychnine represents a further example of the important and, in this particular case, life-threatening agonist–antagonist interactions. Binding of glycine to its receptor induces an increased permeability of the plasma membrane to chloride ions resulting in hyperpolarization and reduced activity of nerve cells, that is, glycine exerts an inhibitory effect on the nervous system. Blockage of the glycine receptors by the antagonist strychnine, that does not elicit a response, results in hyperactivity and severe convulsions.

In addition to acute toxicity, chronic influences exerted by xenobiotics on steroid hormone homeostasis may result in adaptive and proliferative responses in certain tissues. The long-term consequences may involve impairment or loss of the physiological function. Moreover, binding to a specific receptor may cause changes in gene expression and contribute to tumor formation. For example, binding to the Ah receptor (the aryl-hydrocarbon receptor, named on the basis of its interaction with planar, polycyclic aromatic compounds) mediates many of the effects observed with the highly toxic and carcinogenic 2,3,7,8-tetrachlorodibenzodioxin (TCDD). A cytosolic binding protein (cytosolic receptor) has also been identified for peroxisome proliferators, such as clofibrate and diethylhexyl phthalate [135, 136]. This protein has DNA-binding domains and appears to activate gene transcription in the nucleus in a manner analogous to the steroid hormones. The increased cell proliferation caused in target organs such as the liver may be responsible for the carcinogenicity of many peroxisome proliferators. Characteristic examples of receptor–xenobiotic interactions with harmful acute or chronic consequences are summarized in Table 20.

Table 20. Chemicals causing toxic response by interaction with receptors (Ah = aryl hydrocarbon)

Type of receptor	Chemical
Muscarinic receptor	atropine
Glycine receptor	strychnine
Ah receptor	TCDD
Peroxisome proliferator receptor	peroxisome proliferators (clofibrate, diethylhexylphthalate)

3.2.2. *Interference with Excitable Membrane Functions*

The maintenance and stability of excitable membranes is essential to normal physiology. Excitable membranes are critical to the function of nerves and muscles due to their ability to generate and propagate action potentials. Action potentials are elicited by the exchange of ions between the intra- and extracellular compartments, and hence they depend on the normal activity of ion channels and membrane ion pumps.

Xenobiotics may perturb excitable membrane functions in many different ways. Xenobiotics can block sodium channels resulting in toxic effects such as paralysis. For example, tetrodotoxin from the the puffer fish irreversibly blocks the sodium channel along the nerve axon and thus prevents the inward sodium current of the action potential while leaving the outward potassium current unaffected. The marine toxin saxitoxin, which is structurally quite different from tetrodotoxin, also produces its paralyzing effects by blocking sodium channels in excitable membranes in essentially the same manner. The insecticide dichlorodiphenyltrichloroethane (DDT) produces its neurotoxic action by interfering with the closing of sodium channels, which impairs the physiological repolarization of excitable membranes. This results in hyperactivity of the nervous system and repetitive discharges of neurons. The most striking symptoms in poisoned insects or mammals are persistent tremor and convulsive seizures. Other neurotoxins such as cyclodiene insecticides and picrotoxin interact with the γ-aminobutyrate (GABA) receptor in neurons. Blockage of the GABA receptor by these antagonists impairs the transport of chloride ions into the cell, which results in partial depolarisation of the membranes in the absence of adequate signals. The clinical symptoms of the pathophysiological changes can be summarized as a state of uncontrolled excitation. In addition, with cyclodiene insecticides this hyperexcitability is augmented by the inhibition of Ca^{2+}–Mg^{2+}–ATPase, which results in accumulation of intracellular free calcium and increased release of neurotransmitters from storage vesicles (Fig. 48).

Figure 48. Sites of action of chlorinated cyclodiene insecticides on the plasma membrane of nerve cells

Organic solvents have a depressant effect on the CNS that results in narcosis by nonspecific alterations in membrane fluidity due to their lipid solubility rather than by interference with specific ion channels. This depressant effect is not based on certain structural features or specific interactions, that is, it is also observed after inhalation of the inert, but highly lipophilic gas xenon.

3.2.3. *Interference of Xenobiotics with Oxygen Transport, Cellular Oxygen Utilization, and Energy Production*

Continuous, sufficient production of energy in form of adenosine triphosphate (ATP) in specialized cellular organelles (mitochondria) is essential for cell survival and function. The process of cellular energy production requires oxygen, cofactors, and a wide array of specialized enzymes acting in concert. Many chemicals produce their toxic effects by interfering with the transport and cellular utilization of oxygen or with the oxidation of carbohydrates, which is coupled to the synthesis of ATP by oxidative phosphorylation.

The interference with cellular energy production may occur at different sites in the uptake, transport, and cellular utilization of oxygen. Oxygen transport from the lung to tissues may be reduced or blocked by xenobiotics which compete with oxygen for the binding site in the transport protein hemoglobin or which chemically modify this binding site. Carbon monoxide competitively blocks the binding of oxygen to the transport protein hemoglobin. Chemical oxidation of the iron in hemoglobin also impairs oxygen transport. Some xenobiotics oxidize the Fe^{2+} at the oxygen binding site in hemoglobin to Fe^{3+}. Hemoglobin with Fe^{3+}, known as, methemoglobin, can not reversibly bind oxygen. Thus, xenobiotics causing methemoglobinemia (e.g., nitrites, aromatic amines) effectively block oxygen transport.
